Abstract

In this paper, we address the problem of failure detection in a timed discrete event system (TDES). We first introduce the problem of detecting time shift failures in a TDES modeled as a \((\max, +)\)-linear system. Then we propose the definition of an indicator that relies on the \((\max, +)\) algebraic framework and show how it can detect time shift failures in the case of a single output system. Finally, an extension is proposed to deal with multiple outputs.

**Keywords:** Fault detection, Fault diagnosis, Modelling, \((\max, +)\)-Linear Systems, Monitoring, Algebraic approaches.

1 Introduction

This paper addresses the problem of fault monitoring in a timed discrete event system (TDES). Given a flow of timed observations, the problem consists in determining whether the flow of observations results from a normal behavior of the system or an abnormal behavior. The problem of fault diagnosis and monitoring has been extensively investigated in untimed discrete event systems (see [Zaytoon and Lafortune, 2013] for a recent survey). However these contributions do not take into account time as an observable quantity. There are a few monitoring approaches that deal with time. The contributions of [Dousson and Duong, 1999; Pencolé and Subias, 2009; Saddem and Philippot, 2014] are based on formalisms like the chronicles or the causal temporal signatures: these formalisms model partially ordered set of observable events with time constraints. The acquisition of such models can come from the expertise or from automated learning techniques ([Subias et al., 2014]). In [Tripakis, 2002] and [Bouyer et al., 2005], the definition of the fault diagnosis problem is based on timed automata. Finally, other contributions are also based on time Petri nets ([Ghazel et al., 2009]; [Jiroveanu et al., 2013]; [Liu et al., 2014]).

In this paper, we propose to introduce a new way to solve the failure detection problem in TDES by using \((\max, +)\) algebraic techniques ([Baccelli et al., 1992]; [Cohen et al., 1989]). The systems that are considered are timed discrete event systems such as manufacturing systems (for instance assembly lines), transportation systems (for instance airport luggage conveyors) . . . The type of failures that are considered are time shifts, that is: given the flow of observations, how to detect that an unobservable event has occurred on time or with an unexpected positive/negative time shift (i.e. delay in the availability of a piece of equipment in an assembly line, unexpected delays for luggage delivery in the network of conveyors . . .). We propose to solve this problem on \((\max, +)\)-linear systems that are a subclass of TDES that is well-suited to model systems like mentionned above. To perform failure detection, we propose to design indicators for \((\max, +)\)-linear systems that aim at analyzing the current flow of observations and asserting about the presence or the absence of time shift failures within the system. The proposed indicators are defined with \((\max, +)\) dioid operators.

The paper is organized as follows. Section 2 summarizes the necessary mathematical background about \((\max, +)\)-linear systems. Section 3 introduces the problem of comparing time event flows within \((\max, +)\)-linear systems. Section 4 then defines the proposed indicator in the specific case where the system has one output only. Section 5 finally extends the definition to the multiple outputs case.

2 Background on \((\max, +)\)-Linear Systems

This section recalls the mathematical background that will be used throughout the paper. Basically, the studied TDES are modeled as \((\max, +)\)-linear systems and the time shift detection problem will be solved with the residuation theory. For this section, interested reader is invited to peruse [Baccelli et al., 1992, Chap 4] and [MaxPlus, 1991].

2.1 Diod theory

**Definition 1** (Idempotent semiring). An idempotent semi-ring \(\mathcal{D}\) is a set endowed with two inner operations denoted \(\oplus\) and \(\otimes\). The sum \(\oplus\) is associative, commutative, idempotent (i.e. \(\forall a \in \mathcal{D}, a \oplus a = a\)) and admits a neutral element denoted \(\epsilon\). The product\(^1\) \(\otimes\) is associative, distributes over the sum and accepts \(\epsilon\) as neutral element.

An idempotent semiring is said to be complete if it is closed for infinite sums and if the product distributes over infinite sums too. Moreover, due to the

\(^1\)As in usual algebra, \(\otimes\) will be omitted when no confusion is possible.
The set $\mathbb{Z}_{\text{max}} \equiv \mathbb{Z} \cup \{-\infty, +\infty\}$, endowed with the max operator as sum $\oplus$ and the classical sum as product $\otimes$, is a complete idempotent semiring where $\varepsilon = -\infty$, $e = 0$ and $T = +\infty$. On $\mathbb{Z}_{\text{max}}$, the greatest lower bound $\wedge$ takes the sense of the min operator.

**Example 4.** The set of formal series with two commutative variables $\gamma$ and $\delta$, Boolean coefficients in $\{\varepsilon, \delta\}$ and exponents in $\mathbb{Z}$, is a complete idempotent semiring denoted $\mathcal{B}[\gamma, \delta]$ where $\varepsilon = \bigoplus_{n\in\mathbb{Z}} \varepsilon^n \delta^t$ (null series) and $\gamma = \delta^n \delta^t$. A series $s \in \mathcal{B}[\gamma, \delta]$ is written in a single way by $s = \bigoplus_{n\in\mathbb{Z}} s(n,t) \gamma^n \delta^t$ where $s(n,t) = \varepsilon$ or $\delta$.

Graphically, a series of $\mathcal{B}[\gamma, \delta]$ is described by a collection of points of coordinates $(n, t)$ in $\mathbb{Z}^2$ with $\gamma$ as horizontal axis and $\delta$ as vertical axis. Boolean coefficients indicate the presence of a point $s(n,t) = \varepsilon$ or its absence $s(n,t) = \delta$.

**Example 5.** The quotient set of $\mathcal{B}[\gamma, \delta]$ by the modulo $\gamma^*(\delta^{-1})^*$ equivalence relation provides the complete idempotent semiring $\mathcal{M}^{ax}_{\mathbb{Z}}[\gamma, \delta]$. This means that an element of $\mathcal{M}^{ax}_{\mathbb{Z}}[\gamma, \delta]$ is an equivalence class denoted $\gamma^n \delta^t$, gathering all the elements of $\mathcal{B}[\gamma, \delta]$ equivalent modulo $\gamma^*(\delta^{-1})^*$. Neutral elements $\varepsilon$ and $\delta$ are identical to those of $\mathcal{B}[\gamma, \delta]$.

Graphically, the product of a monomial $\gamma^n \delta^t \in \mathcal{B}[\gamma, \delta]$ by $\gamma^*(\delta^{-1})^*$ goes to consider this element in $\mathcal{M}^{ax}_{\mathbb{Z}}[\gamma, \delta]$ as a southeast cone with coordinates $(n, t)$ containing all the monomials equivalent to $\gamma^n \delta^t$. The description of all the points of all the cones induced by the monomials of a series $s \in \mathcal{M}^{ax}_{\mathbb{Z}}[\gamma, \delta]$ corresponds to the maximal representation of $s$. Its minimal representation is obtained by writing only the monomials representing the cones' vertices. Another interesting representation is the dater representation obtained from the maximal representation by writing for each $\gamma^n$ of the series, the greatest corresponding $\delta^t$.

Let $s = \gamma^0 \delta^3 \oplus \gamma^2 \delta^4 \oplus \gamma^3 \delta^7$ be a series of $\mathcal{M}^{ax}_{\mathbb{Z}}[\gamma, \delta]$. Figure 1 shows its maximal representation (all the points of the figure) and its dater representation (only the filled points on the lines). Let us remark that because of equivalence $\gamma^*(\delta^{-1})^*$, $s = \gamma^0 \delta^3 \oplus \gamma^2 \delta^4 \oplus \gamma^3 \delta^7 = \gamma^0 \delta^3 \oplus \gamma^1 \delta^3 \oplus \gamma^2 \delta^4 \oplus \gamma^3 \delta^4 \oplus \gamma^4 \delta^4 \oplus \gamma^5 \delta^7 \oplus \gamma^6 \delta^7 \oplus \gamma^7 \delta^7$ (some points are covered by others as $\gamma^1 \delta^3$ by $\gamma^0 \delta^3$).

### 2.2 Residuation theory

Residuation is a general notion in lattice theory which allows for the definition of "pseudo-inverse" of some isotope maps. In particular, the residuation theory provides optimal solutions to inequalities such as $f(x) \leq b$,

were $f$ is an order-preserving mapping defined over ordered sets. This theory can then be applied over idempotent semiring as follows.

**Definition 6** (Residuated and residual mapping). Let $f : D \to C$ be an isotope mapping, where $D$ and $C$ are complete idempotent semirings. Mapping $f$ is said to be residuated if $\forall b \in C$, the greatest element of subset $\{x \in D \mid f(x) \leq b\}$, denoted $\overset{\circ}{f}(b)$, exists and belongs to this subset. Mapping $f^\sharp$ is called the residual of $f$.

When $f$ is residuated, $f^\sharp$ is the unique isotope mapping such that $f \circ f^\sharp \leq \overset{\circ}{f}$ and $f^\sharp \circ f \geq \overset{\circ}{f}$, where $\overset{\circ}{f}$ and $\overset{\circ}{f}$ are respectively the identity mappings on $C$ and $D$.

**Example 7.** Mapping $R_a : x \mapsto x \otimes a$ defined over a complete idempotent semiring $D$ is residuated. Its residual is usually denoted $R^\sharp_a : x \mapsto x^\sharp a$ and called right quotient. Therefore, $b^\sharp a = x = \bigoplus \{x \mid x \otimes a \leq b\}$. This example can be applied for the product of matrices such as $X \mapsto X \otimes A \in D^{n \times m}$ with $A \in D^{n \times m}$ and $X \in D^{p \times m}$, that is:

$$R_a = X \otimes A \mapsto (X \otimes A)_{ij} = \bigoplus_{k=1}^{n} X_{ik} \otimes A_{kj},$$

and the computation of $B \overset{\circ}{f} A \in D^{p \times n}$ with $B \in D^{p \times m}$ is given by:

$$R^\sharp_{\overset{\circ}{f}}(B) = B \overset{\circ}{f} A = (B \overset{\circ}{f} A)_{ij} = \bigwedge_{k=1}^{m} B_{ik} \overset{\circ}{f} A_{kj}. \quad (1)$$

**Theorem 8** ([MaxPlus, 1991]). Let $D$ be a complete dioid and $A \in D^{n \times m}$ be a matrix. Then, $A \overset{\circ}{f} A$ is a matrix which verifies

$$A \overset{\circ}{f} A = (A \overset{\circ}{f} A)^\ast. \quad (2)$$

### 2.3 Models of (max, +)-linear systems

The complete idempotent semiring $\mathcal{M}^{ax}_{\mathbb{Z}}[\gamma, \delta]$ aims at modeling TDES as flows of events over time while keeping the history of their occurrences. Indeed, in a series of $\mathcal{M}^{ax}_{\mathbb{Z}}[\gamma, \delta]$, a monomial $\gamma^n \delta^t$ is interpreted as follows: the $n^{th}$ event occurs at earliest at time $t$. Equivalence $\gamma^*(\delta^{-1})^*$ deals with obtaining weakly increasing series...
which ensures the conservation of information about previous events with their times.

Typical systems that can be modeled within this formal framework are automated assembly lines, box conveyors... Given a flow \( u \) of input timed events (the presence of a new element to be processed in the assembly line, a new box in the conveyor...), the system’s response is indeed a flow \( y \) of output timed events (delivery of a final product at the end of the assembly line, delivery of a box to its destination...).

The relationship between the inputs \( u \) and the outputs \( y \) of the system is given by the following equation:

\[
y = h \oplus u
\]

where \( h \) is its transfer function.

To be more specific, obtaining this input/output relation comes from the following state representation:

\[
\begin{align*}
x &= Ax \oplus Bu \\
y &= Cx
\end{align*}
\]

where \( A \in \mathcal{M}^{x\times n}_{\mathcal{M}^{x\times n}[\gamma, \delta]} \), \( B \in \mathcal{M}^{x\times n}_{\mathcal{M}^{x\times n}[\gamma, \delta]} \), \( C \in \mathcal{M}^{x\times n}_{\mathcal{M}^{x\times n}[\gamma, \delta]} \), and \( n, p \) and \( q \) refer respectively to the state vector size of the system \((x)\), the input vector size \((u)\) and the output vector size \((y)\). Then, by applying Theorem 2 the input/output relation is obtained \( y = CA^*Bu = hu \). So \( h = CA^* \).

Systems that are fully characterized by Equation (3) or Equation (4) are commonly called \((\max, +)\)-linear systems. Moreover, a C++ library called mimmaxgd

Example 9. Consider an automated assembly line with 3 machines \( M_1 \), \( M_2 \) and \( M_3 \) graphically modeled in Figure 2 by a Timed Event Graph\(^3\) (TEG). Machines \( M_1 \) and \( M_2 \) independently process respectively incoming parts \( u_1 \) and \( u_2 \). For each incoming part, the duration of the process is 2 for machine \( M_1 \) and 3 for machine \( M_2 \). The end of the processing of machines \( M_1 \) and \( M_2 \) is respectively represented by the firing of transition \( x_2 \) and \( x_3 \). Machine \( M_3 \) then assembles one part coming from machine \( M_1 \) with one part coming from machine \( M_2 \), taking respectively 3 and 5 time units to arrive there. The firing of transition \( x_4 \) represents the end of the assembling process. Two assembling processes can be done at the same time and the duration of this process is 2 time units. The complete product is then delivered as the output \( y \) of the line.

The matrices \( A, B \) and \( C \) of the state representation of this MISO (Multiple Inputs - Single Output) system is given in \( \mathcal{M}^{x\times n}_{\mathcal{M}^{x\times n}[\gamma, \delta]} \):

\[
A = \begin{pmatrix}
\gamma^0\delta^0 & \gamma^1\delta^0 & \ldots & \gamma^n\delta^0 \\
\gamma^0\delta^2 & \gamma^1\delta^3 & \ldots & \gamma^n\delta^3 \\
\gamma^0\delta^4 & \gamma^1\delta^5 & \ldots & \gamma^n\delta^5 \\
\gamma^0\delta^6 & \gamma^1\delta^7 & \ldots & \gamma^n\delta^7 \\
\end{pmatrix},
B = \begin{pmatrix}
\gamma^0\delta^0 \\
\gamma^0\delta^2 \\
\gamma^0\delta^4 \\
\gamma^0\delta^6 \\
\end{pmatrix},
C = \begin{pmatrix}
\gamma^0\delta^0 \\
\gamma^2\delta^0 \\
\gamma^4\delta^0 \\
\end{pmatrix}.
\]

In the entries of matrices, the grade of \( \gamma \) shows the backward event shift between transitions (the \( n+1 \)th firing of \( x_1 \) depends (not only) on the \( n \)th firing of \( x_2 \)) and the grade of \( \delta \) shows the backward time shift between transitions (the firing date of \( x_2 \) depends on the firing date of \( x_1 \) plus 2 time units). The point ‘\(' denotes \( \varepsilon \) in the matrices (meaning the absence of connection between transitions).

\[u = \begin{pmatrix}
\gamma^0\delta^0 \\
\gamma^2\delta^0 \\
\gamma^4\delta^0 \\
\end{pmatrix}
\]

\[h = CA^*B = \begin{pmatrix}
\gamma^0\delta^7 & \gamma^1\delta^2 & \gamma^2\delta^9 \\
\gamma^0\delta^6 & \gamma^1\delta^3 & \gamma^2\delta^8 \\
\gamma^0\delta^5 & \gamma^1\delta^4 & \gamma^2\delta^7 \\
\end{pmatrix}
\]

Figure 2: A TEG of an automated assembly line.

The transfer function (which is actually a matrix \( h \in \mathcal{M}^{x\times n}_{\mathcal{M}^{x\times n}[\gamma, \delta]} \), with \( q = 1 \)) of the system is computed:

\[h = CA^*B = \begin{pmatrix}
\gamma^0\delta^7 & \gamma^1\delta^2 & \gamma^2\delta^9 \\
\gamma^0\delta^6 & \gamma^1\delta^3 & \gamma^2\delta^8 \\
\gamma^0\delta^5 & \gamma^1\delta^4 & \gamma^2\delta^7 \\
\end{pmatrix}
\]

the corresponding output is:

\[y = hu = \gamma^0\delta^{12} + \gamma^1\delta^{15} + \gamma^2\delta^{18} + \gamma^3\delta^{21} + \gamma^4\delta^{+\infty}
\]

Input \( u \) and output \( y \) illustrate very well the notion of flows of events over time with the history of their occurrences. In these flows also called trajectories, the numbering of event starts at 0. By taking the example of \( u_1 \) and its monomial \( \gamma^0\delta^2 \), this means that the 0th event (that is the first event of the trajectory) occurs at time 0. When trajectories describe a finite number of production orders or a finite number of treated boxes, they contain a finite number of monomials in which the last monomial is written \( \gamma^0\delta^{+\infty} \). This last monomial means that the \( n \)th event never happens (4th event in \( u \) and \( y \)).

3 Time comparison between flows

As presented in Subsection 2.3, \((\max, +)\)-linear systems are fully characterized by the transfer function \( h \). The relationship between the inputs \( u \) and the outputs \( y \) of the system is actually the functional model of the system. A system is said to be failing as soon as the function of the system does not properly operate, that is as soon as the real output flow of events \( y \) does not match the expected output flow \( \bar{y} \). Suppose now that both \( y \) and \( \bar{y} \) are known, the challenge is to find a way to actually compare \( y \) and \( \bar{y} \) and determine the presence of time shifts between \( y \) and \( \bar{y} \).

We propose here to perform this comparison by using the residuation theory in particular the use of the
right quotient \( \dot{S} \). Let \( s \in M^a_{\text{ax}}[\gamma, \delta] \) be a series, the dater function of \( s \) is the non-decreasing function \( D_s(n) \) from \( \mathbb{Z} \) to \( \mathbb{Z} \) such that \( s = \bigoplus_{n \in \mathbb{Z}} \gamma^n \delta^{D_s(n)} \). The proposed comparison then relies on the use of a time shift function.

**Definition 10** (Time shift function). Let \( a, b \in M^a_{\text{ax}}[\gamma, \delta] \) and their respective dater functions \( D_a(n) \) and \( D_b(n) \), the time shift function representing the time shifts between \( a \) and \( b \) for each \( n \in \mathbb{Z} \) is defined by \( T_{a,b}(n) = D_a(n) - D_b(n) \).

Intuitively speaking, the time shift function associates the time difference between the occurrence of the \( n \)-th event of series \( a \) and the occurrence of the \( n \)-th event of series \( b \). Obviously, \( T_{a,a}(n) = 0, \forall n \in \mathbb{Z} \).

**Theorem 11** ([MaxPlus, 1991]). Let \( a, b \in M^a_{\text{ax}}[\gamma, \delta] \), the time shift function can be bounded as follows:

\[
\forall n \in \mathbb{Z}, \quad D_{b/a}(0) \leq T_{a,b}(n) \leq -D_{a/b}(0).
\]

The lower bound is the minimal shift in the time domain between \( a \) and \( b \) whereas the upper bound is the maximal shift.

Theorem 11 asserts that the comparison between series \( a \) and \( b \) can be reduced to determine the bounds \( D_{b/a}(0) \) and \( -D_{a/b}(0) \) of their time function \( T_{a,b} \). These bounds can be extracted from the series \( b/a \) and \( a/b \). More specifically, by writing these bounds back in series of \( M^a_{\text{ax}}[\gamma, \delta] \):

\[
D_{b/a}(0) \text{ comes from } \gamma^0 \delta^{D_{b/a}(0)} \in b/a,
\]

\[
-D_{a/b}(0) \text{ comes from } \gamma^0 \delta^{D_{a/b}(0)} \in a/b.
\]

These monomials might not appear explicitly in series \( a/b \) and \( b/a \), however they can be revealed by writing them into their dater representations in which each grade of \( \gamma \) present in the series is written.

**Example 12.** For instance, let \( a, b \in M^a_{\text{ax}}[\gamma, \delta] \) such that:

\[
a = \gamma^0 \delta^{12} \oplus \gamma^1 \delta^{15} \oplus \gamma^2 \delta^{18} \oplus \gamma^3 \delta^{21} \oplus \gamma^4 \delta^{+\infty},
b = \gamma^0 \delta^{12} \oplus \gamma^1 \delta^{15} \oplus \gamma^2 \delta^{19} \oplus \gamma^3 \delta^{23} \oplus \gamma^4 \delta^{+\infty}.
\]

As illustrated in Figure 3, it is clear that the minimal time shift is equal to 0 (reached for \( \gamma^0 \) and \( \gamma^1 \)) whereas the maximal time shift is equal to 2.

Computations of \( a/b \) and \( b/a \) provide mathematically these shifts:

\[
a/b = \gamma^0 \delta^{-2} \oplus \gamma^1 \delta^2 \oplus \gamma^2 \delta^6 \oplus \gamma^3 \delta^9 \oplus \gamma^4 \delta^{+\infty},
b/a = \gamma^0 \delta^0 \oplus \gamma^1 \delta^3 \oplus \gamma^2 \delta^7 \oplus \gamma^3 \delta^{11} \oplus \gamma^4 \delta^{+\infty}.
\]

The minimal time shift \( D_{b/a}(0) \) is equal to 0 and is found in the monomial \( \gamma^0 \delta^{D_{b/a}(0)} \) of \( b/a \). This means that for at least one point, series \( a \) and \( b \) contain the same monomial \( \gamma^0 \delta^{12} \) and \( \gamma^1 \delta^{15} \) to be specific). The maximal time shift \( -D_{a/b}(0) \) is equal to 2 and is found in the monomial \( \gamma^0 \delta^{D_{a/b}(0)} \) of \( a/b \) and is illustrated in Figure 4. This means that the biggest distance between \( a \) and \( b \) in the vertical point of view is of 2 time units (between monomials \( \gamma^3 \delta^{21} \in a \) and \( \gamma^3 \delta^{23} \in b \) to be specific).

Back to the problem of comparing the real output \( y \) of the system and its expected output \( \tilde{y} \), Theorem 11 then provides a way to bound the possible time shifts between the events of \( y \) and \( \tilde{y} \). More specifically, bounds on these time shifts are determined as follows.

**Proposition 13** (Bounds on time shifts). Let \( y \) and \( \tilde{y} \in M^a_{\text{ax}}[\gamma, \delta] \), time shifts between \( y \) and \( \tilde{y} \) are in the following interval:

\[
\Sigma_T(y, \tilde{y}) = [D_{y/\tilde{y}}(0); -D_{\tilde{y}/y}(0)]
\]

where \( \gamma^0 \delta^{D_{y/\tilde{y}}(0)} \in y \tilde{y} \) and \( \gamma^0 \delta^{D_{\tilde{y}/y}(0)} \in \tilde{y} y \).

**4 Indicator: the Single Output case**

This section introduces a first failure indicator that can be implemented on \( (\max+, +) \)-linear systems that are composed of a set of inputs \( u \) and one single output \( y \) (called MISO system for short). Figure 2 illustrates such a system. Only the inputs and the output of the system are observable. As stated in Subsection 2.3, the output of a \( (\max+, +) \)-linear system is fully characterized by its transfer function \( h \). By the observation of \( u \), it is therefore possible to compute the expected output of the system, that is:

\[
\tilde{y} = h u.
\]

The indicator in charge of detecting time shift failures then computes the time shift bounds between the real observed output \( y \) and the expected output \( \tilde{y} \).
Definition 14 (Indicator of an observed MISO system). Let \( h \in M_{n \times n}^{\mathbb{R}}[\gamma, \delta]^{s \times p} \) be the transfer function of a MISO (max, +)-linear system, let \( u \in M_{n \times n}^{\mathbb{R}}[\gamma, \delta]^p \) and \( y \in M_{n \times n}^{\mathbb{R}}[\gamma, \delta]^q \) be the observable input and output trajectories of the system, the indicator \( I_{SO} \) of the system is a function:

\[
I_{SO}(u, y) = \begin{cases} 
\text{false if for } \tilde{y} = hu, \Sigma_r(y, \tilde{y}) = [0; 0], \\
\text{true otherwise.} 
\end{cases} 
\]

(6)

The indicator raises an alarm (i.e., it returns true) as soon as the minimal or the maximal time shift bounds determined by Proposition 13 between the observed output \( y \) and its expected counterpart \( \tilde{y} \) are not null. By returning false only when \( \Sigma_r(y, \tilde{y}) = [0; 0] \), it is guaranteed that the indicator will return false only when these bounds are null. Now the remaining question is whether the defined indicator is correct or not.

Definition 15 (Correct indicator). An indicator is correct if it returns true only when the system is failing.

In other words, a correct indicator should never raise a signal, an alarm, as long as the system has no failure. A correct indicator ensures that there are no false positive detection alarms. For this specific indicator, it means that it is correct only if \( \Sigma_r(y, \tilde{y}) \neq [0; 0] \) means the system is indeed failing.

Proposition 16. The indicator \( I_{SO}(u, y) \) is correct.

Proof. To prove that \( I_{SO}(u, y) \) is correct, we need to prove that for any couple of identical trajectories \( (y_i, y_2) \) in \( M_{n \times n}^{\mathbb{R}}[\gamma, \delta] \), \( \Sigma_r(y_i, y_2) = [0; 0] \). Let us consider two identical series \( y_1 \) and \( y_2 \), then \( y_1 \neq y_2 \). Now, let \( x_1 = y_1 \neq y_2 \). According to Theorems 8 and 2, \( x_1 = (x_1)^* = e \oplus \cdots \oplus \gamma^0 \oplus \cdots \). Therefore there always exists in \( y_1 \neq y_2 \) and in \( y_2 \neq y_1 \) a monomial \( e = \gamma^0 \). Thus from Theorem 11 we get \( D_{y_1 \neq y_2}(0) = -D_{y_2 \neq y_1}(0) = 0 \). By Equation (5) the result follows.

Example 17. Let us take back the MISO (max, +)-linear system of Figure 2. When the system is not failing, remember that for the following input:

\[
u = \begin{pmatrix} 
0^2 \oplus 1^1 \delta^1 \oplus 1^2 \delta^2 \oplus 1^3 \delta^3 \oplus 1^4 \delta^4 \oplus 1^5 \delta^5 \oplus 1^6 \delta^{10} \\
\end{pmatrix}
\]

the expected output is:

\[
\tilde{y} = hu = \begin{pmatrix} 
\gamma^0 \delta^{12} \oplus 1^1 \delta^{15} \oplus 1^2 \delta^{18} \oplus 1^3 \delta^{21} \oplus 1^4 \delta^{24} \\
\end{pmatrix}
\]

Now, assume that there is a time failure from transition \( x_1 \) to transition \( x_2 \) which generates a delay of 2 time units (machine \( M_1 \) unexpectedly spends 4 time units to process instead of 2). The observed output is then:

\[
y = \begin{pmatrix} 
\gamma^0 \delta^{12} \oplus 1^1 \delta^{15} \oplus 1^2 \delta^{19} \oplus 1^3 \delta^{23} \oplus 1^4 \delta^{26} \\
\end{pmatrix}
\]

One can see that \( \tilde{y} \) and \( y \) are respectively equal to series \( a \) and \( b \) from Figure 3 so:

\[
\tilde{y} = \begin{pmatrix} 
0^2 \oplus 1^1 \delta^1 \oplus 1^2 \delta^2 \oplus 1^3 \delta^3 \oplus 1^4 \delta^4 \\
\end{pmatrix}
\]

\[
y = \begin{pmatrix} 
\gamma^0 \delta^0 \oplus 1^1 \delta^1 \oplus 1^2 \delta^2 \oplus 1^3 \delta^3 \oplus 1^4 \delta^4 \\
\end{pmatrix}
\]

According to Proposition 13:

\[
\Sigma_r(y, \tilde{y}) = [D_{y \neq \tilde{y}}(0); -D_{\tilde{y} \neq y}(0)] = [0; 2] = \Sigma_r(y, \tilde{y})
\]

Then, by Definition 14, \( I_{SO}(u, y) = \text{true} \), the time shift failure is detected.

5 Extension to the Mutiple Outputs case

The extension to the MIMO (Multiple Inputs Multiple Outputs) case can be done very naturally by the matrix computation of the right quotient given in Equation (1). A MIMO system is failing if at least one of its output is not the expected one. In a MIMO system, observed output \( y \) and expected output \( \tilde{y} \) are column vectors of size \( q \), that is \( y, \tilde{y} \in M_{n \times n}^{\mathbb{R}}[\gamma, \delta]^q \). So, the computations of \( y \neq \tilde{y} \) in \( I_{SO}(u, y) \) will return false.

Example 18 (Indicator of an observed MIMO system). Let \( h \in M_{n \times n}^{\mathbb{R}}[\gamma, \delta]^{q \times p} \) be the transfer function of a MIMO (max, +)-linear system. Let \( u \in M_{n \times n}^{\mathbb{R}}[\gamma, \delta]^p \) and \( y \in M_{n \times n}^{\mathbb{R}}[\gamma, \delta]^q \) be the observable input and output trajectories of the system. The indicator \( I_{MO} \) of the system is a function:

\[
I_{MO}(u, y) = \bigvee_{i=1}^q I_{SO}(u, y_i).
\]

(7)

where \( I_{SO}(u, y_i) \) is a modified version of the single output indicator:

\[
I_{SO}(u, y_i) = \begin{cases} 
\text{false if for } \tilde{y}_i = hu, \Sigma_r(y_i, \tilde{y}_i) = [0; 0], \\
\text{true otherwise.} 
\end{cases}
\]

More precisely:

\[
\Sigma_r(y_i, \tilde{y}_i) = [D_{y_i \neq \tilde{y}_i}(0); -D_{\tilde{y}_i \neq y_i}(0)] = [D_{y_i \neq \tilde{y}_i}(0); -D_{\tilde{y}_i \neq y_i}(0)].
\]

As for the indicator on system with a single output and since \( u \) is observed, \( I_{MO} \) first simulates the system to get the expected output \( \tilde{y} \). Then, thanks to the computation of the right quotient of matrices between \( y \) and \( \tilde{y} \), the distances between each \( y_i \) and \( \tilde{y}_i \) is computed as explained in Section 3.

Proposition 18. The indicator \( I_{MO}(u, y) \) is correct.

Proof. \( I_{MO} \) returns true if there exists at least one index \( i \) such that \( I_{SO}(u, y_i) \) is true. But \( I_{SO}(u, y_i) \) is correct as it is based on the computation of the time shift bounds \( \Sigma_r(y_i, \tilde{y}_i) \) (see Proposition 16). Therefore, as long as the expected output of the system is the real output of the system \( I_{MO} \) will return false.
Example 20. Let the MIMO \((max, +)\)-linear system illustrated Figure 5, with the following state representation:

\[
\begin{aligned}
X &= \begin{pmatrix}
\gamma_0 \delta^2 & \cdots & \gamma_0 \delta^4 \\
\gamma_0 \delta^2 & \cdots & \gamma_1 \delta^4 \\
\gamma_0 \delta^2 & \cdots & \gamma_0 \delta^4 \\
\end{pmatrix} X \oplus \begin{pmatrix}
\gamma_0 \delta^1 \\
\gamma_0 \delta^1 \\
\gamma_0 \delta^1 \\
\end{pmatrix} U, \\
Y &= \begin{pmatrix}
\gamma_0 \delta^3 & \cdots & \gamma_0 \delta^4 \\
\gamma_0 \delta^3 & \cdots & \gamma_0 \delta^4 \\
\gamma_0 \delta^3 & \cdots & \gamma_0 \delta^4 \\
\end{pmatrix} X.
\end{aligned}
\]

and the transfer function:

\[
h = \begin{pmatrix}
\gamma_0 \delta^8 (\gamma_1 \delta^1)^* & \gamma_0 \delta^8 (\gamma_1 \delta^1)^* & \gamma_0 \delta^8 (\gamma_1 \delta^1)^* \\
\gamma_0 \delta^5 (\gamma_1 \delta^1)^* & \gamma_0 \delta^5 (\gamma_1 \delta^1)^* & \gamma_0 \delta^5 (\gamma_1 \delta^1)^* \\
\end{pmatrix}.
\]

Figure 5: A MIMO \((max, +)\)-linear system

By giving the following input:

\[
u = \begin{pmatrix}
\gamma_0 \delta^2 \oplus \gamma_1 \delta^4 \oplus \gamma_3 \delta^8 \\
\gamma_0 \delta^3 \oplus \gamma_1 \delta^5 \oplus \gamma_3 \delta^8 \\
\end{pmatrix},
\]

the expected output is:

\[
\tilde{y} = \begin{pmatrix}
\gamma_0 \delta^8 \oplus \gamma_1 \delta^1 \oplus \gamma_3 \delta^3 \\
\gamma_0 \delta^5 \oplus \gamma_1 \delta^5 \oplus \gamma_3 \delta^3 \\
\end{pmatrix}.
\]

Now, assume that there is a time failure generating a delay of 4 time units between transition \(x_1\) and transition \(x_2\) (the place between these transitions is then labeled with 6 time units instead of 2). The observed output is then:

\[
y = \begin{pmatrix}
\gamma_0 \delta^{12} \oplus \gamma_1 \delta^{14} \oplus \gamma_3 \delta^{16} \\
\gamma_0 \delta^8 \oplus \gamma_1 \delta^{10} \oplus \gamma_3 \delta^{12} \\
\end{pmatrix}.
\]

Computations of \(\tilde{y} \odot y\) and \(y \odot \tilde{y}\) give for output \(y_1\):

\[
(\tilde{y} \odot y)_{11} = \tilde{y}_1 \odot y_1 = \gamma_0 \delta^{-1} \oplus \gamma_1 \delta^0 \oplus \gamma_2 \delta^2 \oplus \gamma_3 \delta^{+\infty},
\]

\[
(\tilde{y} \odot y)_{12} = \tilde{y}_1 \odot y_2 = \gamma_0 \delta^0 \oplus \gamma_1 \delta^1 \oplus \gamma_2 \delta^3 \oplus \gamma_3 \delta^{+\infty}.
\]

So, \(I_{SO}(u, y_1) = true\) because \(\Sigma_T(y_1, \tilde{y}_1) = [0; 1]\). A time shift is detected for this output. About output \(y_2\), we obtain:

\[
(\tilde{y} \odot y)_{22} = \tilde{y}_2 \odot y_2 = \gamma_0 \delta^0 \oplus \gamma_1 \delta^1 \oplus \gamma_2 \delta^3 \oplus \gamma_3 \delta^{+\infty},
\]

\[
(\tilde{y} \odot y)_{22} = \tilde{y}_2 \odot y_2 = \gamma_0 \delta^0 \oplus \gamma_1 \delta^1 \oplus \gamma_2 \delta^3 \oplus \gamma_3 \delta^{+\infty}.
\]

So, \(I_{SO}(u, y_2) = false\) because \(\Sigma_T(y_2, \tilde{y}_2) = [0; 0]\). There is no time shift detected for this output.

Finally, by Definition 18, \(I_{SO}(u, y) = I_{SO}(u, y_1) \lor I_{SO}(u, y_2) = true \lor false = true\). The time failure is detected.

6 Conclusion

This paper introduces the problem of fault detection and diagnosis of TDES by the use of a \((max, +)\) algebraic approach. The use of \((max, +)\) to compute indicators for time shift failures in systems like assembly lines, transportation systems is very natural and relies on the resudiation theory. The set of failure indicators that are defined here are fully characterized by \((max, +)\) operators and are proven to be correct as they rely on the computation of time shift bounds between two timed event flows. The proposed approach has been fully implemented with the minmaxgd C++ library.

This paper is a first step towards a complete diagnostic framework that covers \((max, +)\)-linear systems. Our aim is to extend the model by introducing fault models and then perform more complex diagnostic tasks like fault localisation and identification. The diagnosability question as well as the sensor placement problem will be also investigated within the diagnostic framework over \((max, +)\)-linear systems. In particular, one specific problem in this type of system is that faults can be compensated by synchronization phenomena so that they might totally be silent from a global point of view, and adding local sensors is then necessary.

Another lead to this work is to deal with systems that present time intervals for the duration of processes. In that case, one idea should be to work with bounds of the system behaviors, a fastest with all the minimal times of intervals and a slowest with all the maximal times. This can be very useful for systems where processes times are not exactly known or may vary.
