C-CROC: Continuous and Convex Resolution of Centroidal dynamic trajectories for legged robots in multi-contact scenarios

Pierre Fernbach, Steve Tonneau, Olivier Stasse, Justin Carpentier and Michel Taïx

Abstract—Synthesizing legged locomotion requires planning one or several steps ahead (literally): when and where, and with which effector should the next contact(s) be created between the robot and the environment? Validating a contact candidate implies *a minima* the resolution of a slow, non-linear optimization problem, to demonstrate that a Center Of Mass (COM) trajectory, compatible with the contact transition constraints, exists.

We propose a conservative reformulation of this trajectory gen-8 eration problem as a convex 3D linear program, CROC (Convex 9 10 Resolution Of Centroidal dynamic trajectories). It results from the observation that if the COM trajectory is a polynomial with 11 only one free variable coefficient, the non-linearity of the problem 12 disappears. This has two consequences. On the positive side, in 13 terms of computation times CROC outperforms the state of the 14 art by at least one order of magnitude, and allows to consider 15 interactive applications (with a planning time roughly equal to 16 the motion time). On the negative side, in our experiments our 17 approach finds a majority of the feasible trajectories found by a 18 non-linear solver, but not all of them. Still, we demonstrate that 19 the solution space covered by CROC is large enough to achieve 20 the automated planning of a large variety of locomotion tasks 21 for different robots, demonstrated in simulation and on the real 22 HRP-2 robot, several of which were rarely seen before. 23

Another significant contribution is the introduction of a Bezier curve representation of the problem, which guarantees that the constraints of the COM trajectory are verified continuously, and not only at discrete points as traditionally done. This formulation is lossless, and results in more robust trajectories. It is not restricted to CROC, but could rather be integrated with any method from the state of the art.

 Humanoid robots, legged robots, motion planning

I. INTRODUCTION

THIS paper is concerned with the issue of planning multicontact motions for legged robots in human environments.

33

The term "multi-contact motion" has been proposed to 37 distinguish the problem from the gaited locomotion one [1], 38 [2]. Gaited motions result from the contact interactions created 39 and broken periodically between the end effectors and a flat 40 terrain. The multi-contact problem is more general as it can 41 include non horizontal contacts, and is not restricted to a cyclic 42 strategy. This results in a combinatorial problem in the choice 43 of the contacts being created. It also requires a more complex 44 formulation of the dynamics that govern the motion. This non-45 linear problem remains open to this date. 46

Fig. 1: An instance of the transition feasibility problem: can we guarantee that the contact sequence shown in this picture can be used to produce a feasible motion for the robot? To address this issue in this example we need to account for 9 different contact phases (including phases where the effector is flying, as displayed in the fourth image).

One key issue of multi-contact locomotion consists in choosing contact locations such that the contacts can be broken or created at a given time without violating dynamic or geometric constraints. To tackle this issue one option is to simultaneously optimize the contact locations and the motion of the robot. The problem is non-linear, though promising results have been obtained using approximations [3]–[6]. Such approximations include ignoring collision avoidance or considering a point-mass model.

The present paper lies in the continuity of an alternate approach that decomposes the problem into a sequence of smaller ones [7]–[11].In such approaches, the computation of a contact plan is achieved prior to the motion generation. This simplifies the problem, but introduces the question of the validity (feasibility) of the contact plan.

Those approaches thus face the same fundamental challenge: how to make sure that the solution computed using a reformulation of the multi-contact problem provides a straightforward solution to the original problem? As an example, both families of approaches propose contributions that rely on a model-based approach called the *centroidal model*, which only considers the dynamics of the Center Of Mass of the robot,

rather than the whole-body dynamics. This model introduces 69 approximations regarding the geometric constraints that lie on 70 the robot, and also regarding the angular momentum variation 71 induced by the motion of the rigid bodies that compose the 72 robot. The question is then to determine whether it is possible 73 to formulate additional constraints on the centroidal dynamics, 74 that would take into account the whole-body constraints. 75

Finding what we call the "reduction properties": formal 76 theorems or empirical properties that will prove the validity of 77 the problem decomposition or approximation, is the original 78 scientific issue that we propose to tackle. 79

In particular, in this work, we consider what we call the 80 transition feasibility problem: given two states of the robot, 81 can we guarantee that there exists (or not) a dynamically 82 and kinematically consistent motion that connects these two 83 states (Figure 1)? Being able to address efficiently this issue 84 is desirable in the context of the authors' framework, but 85 not only, as the objective is to provide additional guaran-86 tees to the centroidal model, and to improve significantly 87 its computational efficiency. From an applicative point of 88 view, its resolution would also allow to address the N-step 89 capturability problem [12]-[14]: given the current state of the 90 robot, determine whether it will be able to come to a stop 91 without falling in at most N steps ($N \ge 0$). This issue is 92 very important to guarantee the safety of the robot and its 93 surroundings. 94

A. The transition feasibility in a divide and conquer context 95

Over the last few years, we have proposed a methodology 96 to tackle the multi-contact motion problem, which relies on 97 its decomposition into three sub-problems solved sequentially 98 (Figure 2). This approach follows a "divide and conquer" 99 pattern, with the idea that three sub-problems should be ad-100 dressed in a sequentially independent fashion: \mathcal{P}_1 , the planning 101 of a trajectory for the root of the robot, \mathcal{P}_2 the generation 102 of a discrete contact sequence along the root's trajectory 103 and \mathcal{P}_3 the generation of a whole-body motion from this 104 contact sequence. We have proposed several contributions 105 to each sub-problem [15]-[17], and built a prototype that 106 demonstrated its capability to find solutions for various robots 107 and environments, with interactive computation times (a few 108 seconds of computation for several steps of motion). 109

The decoupling between each sub-problem allows to break 110 the complexity, and comes with a cost that is the introduction 111 of a feasibility problem: each sub-problem must be solved in 112 the feasibility domain of the next sub-problems: ie. there must 113 exist a sequence of contacts (problem \mathcal{P}_2) that can follow the 114 root's trajectory found (solution of \mathcal{P}_1), and similarly there 115 must exist a feasible whole-body motion (problem \mathcal{P}_3) from 116 the computed contact sequence (solution of \mathcal{P}_2). The latter 117 problem is an instance of the transition feasibility problem 118 that we address in this paper (The former was considered in 119 [15]). 120

It is important to observe that in this context, establishing 121 the transition feasibility as fast as possible is crucial: \mathcal{P}_2 is 122 a combinatorial problem, which implies that many contact 123 sequences (thousands) must possibly be tried before finding 124 a feasible contact sequence. 125

Recent contributions have proposed centroidal trajectory 126 generation methods that could theoretically be used to answer 127 the transition feasibility problem [18]-[20]. However, because 128 of the combinatorial aspect of contact planning, the computa-129 tional time required by these methods is too important to use 130 a trial-and-error approach to verify the feasibility. Caron et al. 131 recently proposed a computationally efficient method [21], but 132 its application range is restricted to single-contact to single-133 contact transitions. 134

The work that is the closest to the present paper is the 135 one of Ponton et al. [22]. By integrating the dynamic con-136 straints inside a mixed-integer programming problem [4], they 137 addressed the transition feasibility problem at the contact 138 planning level. However the constraints are only approximated 139 through a convex relaxation (convex approximation is also 140 done in [23]), and mixed-integer approaches remain subject to 141 combinatorial explosion. The main difference between their 142 formulation and the method presented in this paper lies in 143 the fact that the presented method uses conservative dynamics 144 constraints rather than approximated ones, and is also more 145 computationally efficient. 146

B. Contributions

The main contribution is the formulation of a transition 150 feasibility criterion, able to test if there exists a kinematically 151 and dynamically valid motion that connects two states of the 152 robot, called CROC (which stands for Convex Resolution Of 153 Centroidal dynamic trajectories). Thanks to a conservative and 154 convex reformulation of the problem, this is achieved in a 155 fraction of the computational cost required by standard non-156 linear solvers. This method also produces a feasible CoM tra-157 jectory. This trajectory can be used as a valuable initial guess 158 by a non-conservative non-linear solver to converge towards 159 an optimal solution. Noticeably, this formulation is, along 160 with [24], one of the few able to continuously guarantee 161 that the computed trajectories respect the constraints of 162 the problem, when other approaches require to discretize the 163 trajectory and check punctually the constraints. 164

Thanks to this criterion, we can provide strong guarantees 165 that a computed contact sequence will lead to a feasible 166 whole body motion. This also results in a major technical contribution, as we obtain and demonstrate a framework able 168 to automatically and robustly generate complex motions, both in simulation and on the real HRP-2 robot. The framework is 170 an extension of our previous works: [15] [16] for \mathcal{P}_1 and \mathcal{P}_2 , 171 and [17] [18] for \mathcal{P}_3 .

This paper is organized as following. In section II, we recall 173 the formal definition of the problem. The main contribution 174 of the paper is presented in section III. We then introduce our complete framework in section V. Finally, we present our 176 experimental results in section VI.

C. Situation of the contribution with respect to the authors 178 previous work 179

The present paper is an extension of an IROS conference 180 paper [25], where we introduce a convex optimization method 181

to solve the transition feasibility problem. Our previous formu-182 lation, as others in the community, is limited by the necessity 183 to use of the double description method [26], an unstable 184 mean to compute the linear constraints that apply to the 185 problem [18], which allows for fast computations. As for 186 all existing methods, it also requires a discretization of the 187 solution trajectory, such that the constraints of the problem are 188 only checked at specific instants. This behavior is unsafe as 189 the trajectory between each discretization point is unchecked 190 and may not respect the constraints, as illustrated in Figure 3. 191 In [25], we proposed a continuous formulation of the problem 192 in the simple case of a motion without contact changes, 193 where the trajectory is linearly constrained. In this paper, we 194 extend this continuous formulation to the general setting of 195 a motion with any number of contact transitions. As we will 196 see, this extension is not trivial as it requires handling the 197 non-convex constraint of belonging to a union of polytopes. In 198 addition, this formulation removes the need for discretization 199 of the centroidal trajectory, guaranteeing that the constraints 200 are respected along the whole trajectory. This continuous 201 formulation is also fast enough to avoid using the double 202 description method. The computational gain results from the 203 lower number of variables required to satisfy the constraints. 204

²⁰⁵ We advocate for its adoption for any centroidal generation method.

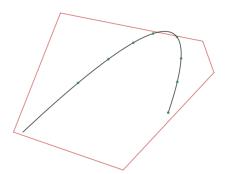

Fig. 3: Example of an invalid solution found by a discretized method. The red lines represent the constraints, wile the black curve is the solution and the green dots are the discretization points. All the discretization points satisfy the constraints while the curve clearly violates them.

Sections II and III present important similarities with respect 207 to [25]. The novelty appears from section III-D, where we present a continuous formulation able to deal with contact 209 switching during the trajectory. 210

The other sections of the paper are also novel. These novelties include the completion of our experimental framework, which enables us to validate our method on several experiments on the real robot. We also provide an empirical analysis of the performances of our method with respect to a state-of-the-art nonlinear solver, in terms of success rate and computation times. 211

II. PROBLEM DEFINITION

We define the transition feasibility problem as follows. 219 Given two configurations of a robot; given the contact loca-220 tions associated to these two configurations; given the position, 221 velocity and acceleration of the Center Of Mass (COM) of the 222 robot at these two configurations; can we guarantee that there 223 exists a feasible motion that connects the two configurations? 224 A feasible motion should respect the kinematic constraints 225 of the robot, as well as the dynamics expressed at its CoM. 226 Depending on the use case, some constraints may be removed 227 (for instance if the end configuration is unknown, or if the 228 problem is simply to put the robot to a stop). 229

Thus, in this work we define the transition feasibility problem with respect to the centroidal dynamics of a robot, as now commonly done in the legged robotics community [27], [19], [18]. In this section we provide some formal definitions that are used in the rest of the paper. 234

A. Contact sequence and state

A legged motion can be discretized into a sequence of 236 contact phases. Each contact phase defines a number of 237 active contacts, and their locations remain constant during 238 the phase. Thus, each contact phase constrains kinematically 239 and dynamically the motion of the robot. Within a contact 240 sequence, each adjacent contact phase differs by exactly one 241 contact creation or removal (for instance when walking, the 242 contact sequence is gaited and alternates simple and double 243 support phases). The considered contact surfaces are assumed 244 to be rectangular (4 extreme points on each foot) for humanoid 245 robots, and punctual for quadrupedal robots. 246

218

We define a state $\mathbf{x} = (\mathbf{c}, \dot{\mathbf{c}}, \ddot{\mathbf{c}}) \in \mathbb{R}^3 \times \mathbb{R}^3 \times \mathbb{R}^3$ as the 247 triplet describing the COM position, velocity and acceleration. 248 To indicate that a state is compatible with the dynamic and 249 kinematic constraints associated with a contact phase $p \in \mathbb{N}$, 250 we use the superscript notation $\mathbf{x}^{\{p\}} = (\mathbf{c}^{\{p\}}, \dot{\mathbf{c}}^{\{p\}}, \ddot{\mathbf{c}}^{\{p\}}).$ 251

Given two states $\mathbf{x}_{q}^{\{p\}}$ and $\mathbf{x}_{q}^{\{q\}}$ with $q \geq p$, the transition 252 feasibility problem consists in determining whether there ex-253 ists a feasible trajectory $\mathbf{c}(t), t \in \mathbb{R}^+$ of duration $T \in \mathbb{R}^+$, 254 which connects exactly $\mathbf{x}_{s}^{\{p\}}$ and $\mathbf{x}_{q}^{\{q\}}$. 255

B. Centroidal dynamic constraints on $\mathbf{c}(t)$ 256

For a contact phase $\{p\}$ of duration T, for any $t \in [0, T]$ the 257 centroidal dynamic constraints are given by the Newton-Euler 258 equations. These constraints form a convex cone (or polytope), 259 which can be expressed under two different formulations, the-260 oretically equivalent [28]–[30], but really different in practice. 261 In this paper we present and discuss both formulations. 262

1) Equality constraint representation (or force formula-263 *tion*): The Newton-Euler equations are: 264

$$\begin{bmatrix} m(\ddot{\mathbf{c}} - \mathbf{g}) \\ m\mathbf{c} \times (\ddot{\mathbf{c}} - \mathbf{g}) + \dot{\mathbf{L}} \end{bmatrix} = \begin{bmatrix} \mathbf{I}_3 & \dots & \mathbf{I}_3 \\ \hat{\mathbf{p}}_1 & \dots & \hat{\mathbf{p}}_{nc} \end{bmatrix} \mathbf{f}$$
(1)

Where : 265

- *m* is the total mass of the robot; 266
- *nc* is the number of contact points; 267
- $\mathbf{p}_i \in \mathbb{R}^3, 1 \leq i \leq nc$ is the location of the i-th contact 268 point; ¹ 269
- $\mathbf{f} = [\mathbf{f}_1, \mathbf{f}_2, ..., \mathbf{f}_{nc}]^T \in \mathbb{R}^{3nc}$ is the stacked vector of 270 contact forces applied at each contact point; 271

• $\mathbf{g} = \begin{bmatrix} 0 & 0 & -9.81 \end{bmatrix}^T$ is the gravity vector; 272

- $\dot{\mathbf{L}} \in \mathbb{R}^3$ is the time derivative of the angular momentum 273 (expressed at c). 274
- $\hat{\mathbf{p}}_i$ denotes the skew-symmetric matrix of \mathbf{p}_i . 275

The contact forces are further constrained to lie in their so-276 called friction cone, which we conservatively linearize with 277 four generating rays. Thus f has the form $f = V\beta$, where 278 $\mathbf{V} \in \mathbb{R}^{3nc \times 4nc}$ is the matrix containing the diagonally stacked 279 generating rays of the friction cone of each contact point and 280 $\boldsymbol{\beta} \in \mathbb{R}^{4nc+}$ is a variable. 281

This formulation has the disadvantage of introducing a large 282 number of variables associated to the contact forces (one 283 vector β for each instant where the constraints are verified). 284

2) Inequality constraint representation (or Double Descrip-285 tion formulation): Because the set of admissible contact forces 286 is a polytope, it is possible to use an equivalent "face represen-287 tation" of the constraints that applies both to the center of mass 288 and the angular momentum quantities. With this formulation, 289 the force variables disappear: 290

$$\mathbf{H}\underbrace{\begin{bmatrix} m(\ddot{\mathbf{c}} - \mathbf{g}) \\ m\mathbf{c} \times (\ddot{\mathbf{c}} - \mathbf{g}) + \dot{\mathbf{L}} \end{bmatrix}}_{\mathbf{w}} \leq \mathbf{h}$$
(2)

where H and h are respectively a matrix and a vector defined 291 by the position of the contact points, their normal and their 292

friction coefficients. As this matrix and vector are uniquely defined for a contact phase, we note them with the superscript 294 $\{p\}$ for a contact phase p.

With this formulation, the dimension of the problem is greatly reduced. However, the computation of the matrices $\mathbf{H}^{\{p\}}$ and $\mathbf{h}^{\{p\}}$ is a non-trivial operation called the double description method [26]. It is computationally expensive, and subject to occasional failures.

In the following theoretical sections, we will use the in-301 equality formulation because we believe our contribution is 302 more intuitive with this representation. In terms of implemen-303 tation the equality formulation is more reliable but slower. 304 However we show that under our formulation the computation 305 times remain in the same order of magnitude with both 306 formulations.

3) The dynamic constraints are not convex: Because of the cross product between c and \ddot{c} in the equations (1) and (2), the constraints are bi-linear, leading to a non-convex problem 310 to solve.

C. Centroidal kinematic constraints on $\mathbf{c}(t)$

Each active contact also introduces a kinematic constraint 313 on $\mathbf{c}(t)$, depending of the placement of the end-effectors of the 314 robot. We use a linear constraint formulation to represent this 315 constraint depending on the 6D positions of each active contact 316 frames. They give us a necessary but not sufficient condition 317 for the kinematic feasibility (evaluated and discussed in section 318 IV-G). We refer the reader to [31] for the computation of these 319 constraints. For a given contact phase $\{p\}$ this constraint can 320 be expressed as : 321

$$\mathbf{K}^{\{p\}}\mathbf{c} \le \mathbf{k}^{\{p\}} \tag{3}$$

III. CONVEX FORMULATION OF THE TRANSITION PROBLEM

As previously proposed [25], in order to determine the 324 existence of a valid centroidal trajectory $\mathbf{c}(t)$, we formulate 325 the problem as a convex one by getting rid of the non-linear 326 constraints induced by the cross product operation $\mathbf{c} \times \ddot{\mathbf{c}}$. To 327 achieve this we impose a conservative condition on $\mathbf{c}(t)$. 328

However, a significant contribution with respect to [25] and 329 other contributions is a continuous reformulation of the prob-330 lem, which guarantees that the resulting trajectory is always 331 valid. Indeed, traditionally the constraints are only verified at 332 specific points of the trajectory, using a discretization step 333 that must be carefully calibrated to avoid an explosion in 334 the number of variables and constraints, while guaranteeing 335 that the constraints will not be violated in between. Figure 3 336 illustrates the violation of the constraints. 337

A. Reformulation of $\mathbf{c}(t)$ as a Bezier curve

Let us assume that $\mathbf{c}(t)$ is described by an arbitrary polyno-339 mial of degree n of unknown duration T. In such case, without 340 loss of generality, $\mathbf{c}(t)$ is equivalently defined as a constrained 341 Bezier curve of the same degree n: 342

$$\mathbf{z}(t) = \sum_{i=0}^{n} B_i^n (t/T) \mathbf{P}_i \tag{4}$$

293

295

296

307 308 309

311

312

322

323

¹As commonly done, in the case of rectangular contacts (like most robot's feet) we define a contact point at each vertex of the rectangle.

355

356

where the B_i^n are the Bernstein polynomials and the \mathbf{P}_i are the control points.

With this formulation we can easily constrain the initial or final positions, velocity or any other derivatives by setting the value of the control points. To exactly connect two states $\mathbf{x}_s = (\mathbf{c}_s, \dot{\mathbf{c}}_s, \ddot{\mathbf{c}}_s)$ and $\mathbf{x}_g = (\mathbf{c}_g, \dot{\mathbf{c}}_g, \ddot{\mathbf{c}}_g)$, we thus need at least 6 control points to ensure that the following constraints are verified:

- $\mathbf{P}_0 = \mathbf{c}_s$ and $\mathbf{P}_n = \mathbf{c}_g$ guarantee that the trajectory starts and ends at the desired locations;
- $\mathbf{P}_1 = \frac{\dot{\mathbf{e}}_s T}{n} + \mathbf{P}_0$ and $\mathbf{P}_{n-1} = \mathbf{P}_n \frac{\dot{\mathbf{e}}_g T}{n}$ guarantee that the trajectory initial and final velocities are respected;

• $\mathbf{P}_2 = \frac{\ddot{\mathbf{c}}_s T^2}{n(n-1)} + 2\mathbf{P}_1 - \mathbf{P}_0$ and $\mathbf{P}_{n-2} = \frac{\ddot{\mathbf{c}}_g T^2}{n(n-1)} + 2\mathbf{P}_{n-1} - \mathbf{P}_n$ guarantee that the initial and final accelerations are respected.

357 Depending on the considered problem, some constraints 358 on the boundary positions, velocities or accelerations can be 359 removed, without changing the validity of our approach. For 360 instance, if the objective is simply to put the robot to a stop, 361 the end velocities and accelerations can be set to zero, while 362 the end position is left unconstrained. We can also extend this 363 to any degree and add constraints on initial or final jerk or 364 higher derivatives and automatically compute the position of 365 the control points with a symbolic calculus script such as the 366 one that we provide at the url². We only need to compute the 367 equation of the control points once and for all so we do not 368 need to compute them at runtime. In the following equations, 369 we use a curve of degree 6 with the constraints on initial and 370 final position, velocity and acceleration as described above, 371

³⁷² and the same reasoning applies to all cases.

373 B. Conservative reformulation of the transition problem

We now constrain c(t) to be a Bezier curve of degree n = 6. This is a conservative approximation of the transition problem as it does not cover the whole solution space.

As we already need 6 control points to ensure that we connect exactly the two states, this leaves a free control point $\mathbf{P}_3 = \mathbf{y}$:

$$\mathbf{c}(t,\mathbf{y}) = \sum_{i \in \{0,1,2,4,5,6\}} B_i^6(t/T) \mathbf{P}_i + B_3^6(t/T) \mathbf{y}$$
(5)

In this case, y and T are the only variables of the problem. For the time being, we fix T to a constant value. We derive twice to obtain $\ddot{\mathbf{c}}(t)$, and compute the cross product to get the expression of $\mathbf{w}(t)$:

$$\mathbf{w}(t) = \begin{bmatrix} m(\ddot{\mathbf{c}} - \mathbf{g}) \\ m\mathbf{c} \times (\ddot{\mathbf{c}} - \mathbf{g}) + \dot{\mathbf{L}} \end{bmatrix}$$
(6)

The non-convexity of the problem disappears, because the cross product of y by itself is 0, and all other terms are either constant or linear in y. w(t, y) is thus a six-dimensional Bezier curve of degree 2n - 3 [32] (9 in this case) linearly dependent of y:

$$\mathbf{w}(t, \mathbf{y}) = \sum_{i \in \{0..9\}} B_i^9(t/T) \mathbf{P}_{\mathbf{w}i}(\mathbf{y}) + \dot{\mathbf{L}}(t)$$
(7)

where $\mathbf{P}_{\mathbf{w}i}(\mathbf{y}) \in \mathbb{R}^6$ are the control points of $\mathbf{w}(t,\mathbf{y})$ 389 expressed as : 390

$$\mathbf{P}_{\mathbf{w}i}(\mathbf{y}) = \mathbf{P}_{\mathbf{w}i}^{y} \mathbf{y} + \mathbf{P}_{\mathbf{w}i}^{s} \tag{8}$$

The $\mathbf{P}_{\mathbf{w}i}^{y} \in \mathbb{R}^{6\times 3}$ and $\mathbf{P}_{\mathbf{w}i}^{s} \in \mathbb{R}^{6}$ are constants that only 391 depend on the control points \mathbf{P}_{i} of $\mathbf{c}(t, \mathbf{y})$ and of T. 392

In what follows, for the sake of simplicity, we assume 393 $\mathbf{L}(t) = \mathbf{0}$. This is not a limitation: if we express $\mathbf{L}(t)$ as 394 a polynomial in the problem the following reasoning stands. 395 One way to include $\mathbf{L}(t)$ is to represent it as a Bezier curve 396 with one or more free variables. However guaranteeing that we 397 can generate a whole-body motion that tracks a variable $\mathbf{L}(t)$ 398 requires additional information on the whole-body motion, 399 which we leave as future work [19], [33], [34]. 400

The existence of a valid trajectory $\mathbf{c}(t)$ can thus be determined by solving a convex problem.

C. Application for a motion with no contact switch

We first consider the case where p = q = 1.

1) Discrete formulation: Using a discretization step Δt , we discretize $\mathbf{c}(t, \mathbf{y})$ and $\mathbf{w}(t, \mathbf{y})$ over T as follows: 406

$$\mathbf{c}(j\Delta t, \mathbf{y}) = \mathbf{c}_j^y \mathbf{y} + \mathbf{c}_j^s \\ \mathbf{w}(j\Delta t, \mathbf{y}) = \mathbf{w}_j^y \mathbf{y} + \mathbf{w}_j^s$$

$$(9)$$

Where \mathbf{c}_{j}^{y} , \mathbf{c}_{j}^{s} , \mathbf{w}_{j}^{y} and \mathbf{w}_{j}^{s} are constants given by ⁴⁰⁷ $\mathbf{P}_{\{0,1,2,4,5,6\}}$, the total duration T and the time step $j\Delta t$. j ⁴⁰⁸ belongs to the phase set $J^{\{p\}} : \{j \in \mathbb{N} : 0 \leq j\Delta t \leq T^{\{p\}}\}$. ⁴⁰⁹ Given these expressions, we can replace $\mathbf{w}(t)$ in (2) by its ⁴¹⁰ value at each discretization point $j\Delta t$:

$$\mathbf{H}^{\{p\}}\mathbf{w}_{j}^{y}\mathbf{y} \le \mathbf{h}^{\{p\}} - \mathbf{H}^{\{p\}}\mathbf{w}_{j}^{s}$$
(10)

By proceeding similarly for the kinematic constraint (3), we can formulate the following linear feasibility problem (FP) in 3 dimensions: 414

With this discrete formulation the number of constraints in 415 the problem is proportional to the number of discretization 416 points. Moreover, the constraints are verified only at the 417 discretization points, which leaves a risk that a part of the 418 solution trajectory between two discretization points does not 419 satisfy the constraints of the problem (Figure 3). Choosing the 420 number of discretization steps is thus a compromise between 421 the computation time (which depends on the number of 422 constraints) and the risk of finding a solution partially invalid. 423 This is a well-known issue when relying on discretization 424 methods. 425

403

²http://stevetonneau.fr/files/publications/iros18/derivate.py

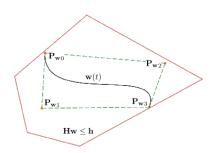

Fig. 4: A bezier curve is comprised in the convex hull of its control points. In this abstract view, the red polygon represents the 6D constraints on $\mathbf{w}(t)$. If the control points $\mathbf{P}_{\mathbf{w}i}$ of $\mathbf{w}(t)$ satisfy the constraints, then the complete curve satisfies the constraints.

Continuous formulation: Alternatively, in [25] we proposed a continuous formulation of this problem, only valid
for the case where no contact transition occurs. We recall
this formulation below as it is fundamental for the following section.

Using the fact that a Bezier curve is comprised in the convex 431 hull of its control points, the main idea of this formulation is to 432 express the kinematic constraints (3) on the control points P_i 433 of $\mathbf{c}(t, \mathbf{y})$ and the dynamic constraints (2) on the control points 434 $\mathbf{P}_{\mathbf{w}i}(\mathbf{y})$ of $\mathbf{w}(t, \mathbf{y})$ (see Figure 4). Constraining the control 435 points of w(t, y) to satisfy the constraints of the trajectory 436 is *a priori* a conservative approach that further constrains the 437 solution space (we will see that this limitation can be easily 438 overcome). However, this approach allows for a continuous 439 solution to the problem and guarantees that the trajectory is 440 entirely valid. 441

Assuming that the start and goal states are feasible (otherwise the problem has no solution), for the kinematic constraints we only need to find a **y** that satisfies the constraints. For the dynamic constraints all the control points $\mathbf{P}_{\mathbf{w}i}(\mathbf{y})$ must satisfy the equation (2), given the expression (8) we can express the dynamic constraints as follow:

$$\mathbf{H}^{\{p\}}\mathbf{P}_{\mathbf{w}i}^{y}\mathbf{y} \le \mathbf{h}^{\{p\}} - \mathbf{H}^{\{p\}}\mathbf{P}_{\mathbf{w}i}^{s}, \forall i \in [0, 2n-3]$$
(12)

⁴⁴⁸ Finally, we can reformulate the discretized Linear Feasibil-⁴⁴⁹ ity Problem (11) in a continuous fashion:

c >

find y
s. t.
$$\mathbf{K}^{\{p\}}\mathbf{y} \leq \mathbf{k}^{\{p\}}$$
 (13)
 $\mathbf{H}^{\{p\}}\mathbf{P}_{\mathbf{w}^{j}}^{y}\mathbf{y} \leq \mathbf{h}^{\{p\}} - \mathbf{H}^{\{p\}}\mathbf{P}_{\mathbf{w}^{j}}^{s}, \forall i$

In this case, the whole trajectory necessarily satisfies the constraints everywhere, as they form a convex set.

452 D. Application to a motion with one contact switch

We now consider the case where q = p + 1. In this case we define $T^{\{p\}}$ and $T^{\{q\}}$ as the time spent in each phase, such that $T = T^{\{p\}} + T^{\{q\}}$.

When a contact switch occurs during a motion, the constraints applied to the COM trajectory change at the switching time $t = T^{\{p\}}$. When $t < T^{\{p\}}$, the constraints of phase $\{p\}$ must be applied and conversely, the constraints of phase $\{q\}$ must be applied and when $t > T^{\{p\}}$. At $t = T^{\{p\}}$, the definition constraints of both phases must be applied.

1) Discrete formulation: Adapting the discretized FP (11) 462 to this case is straightforward: the formulation remains the 463 same, with the only difference that the constraints that must 464 be verified at each discretized point change at $t = T^{\{p\}}$ and 465 $t > T^{\{p\}}$. We thus have 3 sets of constraints in this case: 466 one for each of the two phases, plus one for the transition 467 time $t = T^{\{p\}}$ where the constraints of both phases apply. We 468 define $J^{\{q\}}: \{j \in \mathbb{N}, T^{\{q-1\}} \leq j\Delta t \leq T^{\{q\}}\}$ and obtain the 469 following FP: 470

find y

$$\mathbf{s.t.} \quad \mathbf{E}_{j}^{\{z\}} \mathbf{y} \le \mathbf{e}_{j}^{\{z\}} \quad , \forall j \in J^{\{z\}}, \forall z \in \{p,q\}$$
(14)

2) Continuous formulation: In this case, since w(t) spans 471 2 distinct sets of linear inequalities, the convex hull of its 472 control points is not guaranteed to lie in the constraint set. 473 The key idea, unlike Lengagne et al. [24], is to fall back 474 to the case where no contact switch occurs, by considering 475 two curves that continuously connect at the switching time 476 $T^{\{p\}}$. A similar approach has been proposed before, in the 477 context of UAVs [35], with the difference that in our case the 478 continuity of the trajectory is guaranteed by the De Casteljau 479 decomposition algorithm. This algorithm divides the original 480 curve into two curves $\mathbf{c}(t, \mathbf{y})$, each curve being subject to the 481 constraints of their respective contact phase (see Figure 5). 482 The result is thus the expression of the control points of two 483 Bezier curves $\mathbf{c}_{\{p\}}(t, \mathbf{y})$ and $\mathbf{c}_{\{q\}}(t, \mathbf{y})$ with the same degree 484 as the original curve, such that : 485

$$\begin{cases} \mathbf{c}_{\{p\}}(t, \mathbf{y}) = \mathbf{c}(t, \mathbf{y}) & \forall t \in [0; T^{\{p\}}] \\ \mathbf{c}_{\{q\}}(t, \mathbf{y}) = \mathbf{c}(t, \mathbf{y}) & \forall t \in [T^{\{p\}}; T] \end{cases}$$
(15)

The De Casteljau decomposition guarantees that $\mathbf{c}_{\{p\}}(T^{\{p\}}, \mathbf{y}) = \mathbf{c}_{\{q\}}(T^{\{p\}}, \mathbf{y})$, and that the composition of the curves in infinitely differentiable (\mathcal{C}^{∞}), as it is strictly equivalent to $\mathbf{c}(t, \mathbf{y})$. The control points of the new curves are linearly dependent on the control points of the original un-split curve, and thus have the following form: 490

$$\mathbf{c}_{\{z\}}(t,\mathbf{y}) = \sum_{i=0}^{n} B_i^n(t/T^{\{z\}}) \mathbf{P}_i^{\{z\}}(\mathbf{y}) \quad \forall z \in \{p,q\} \quad (16)$$

where the $\mathbf{P}_i^{\{z\}}(\mathbf{y})$ have the form:

$$\mathbf{P}_{i}^{\{z\}}(\mathbf{y}) = \mathbf{P}_{i}^{y\{z\}}\mathbf{y} + \mathbf{P}_{i}^{s\{z\}}$$
(17)

with
$$\mathbf{P}_i^{y\{z\}}$$
 and $\mathbf{P}_i^{s\{z\}}$ constants.

It follows that $\mathbf{w}_{\{p\}}(t, \mathbf{y})$ and $\mathbf{w}_{\{q\}}(t, \mathbf{y})$ are also linearly dependent of \mathbf{y} :

$$\mathbf{w}_{\{z\}}(t, \mathbf{y}) = \sum_{j=0}^{2n-3} B_j^{2n-3}(t/T^{\{z\}}) \mathbf{P}_{\mathbf{w}j}^{\{z\}}(\mathbf{y})$$
with $\mathbf{P}_{\mathbf{w}j}^{\{z\}}(\mathbf{y}) = \mathbf{P}_{\mathbf{w}j}^{y\{z\}} \mathbf{y} + \mathbf{P}_{\mathbf{w}j}^{s\{z\}}, \forall z \in \{p, q\}$

$$(18)$$

492

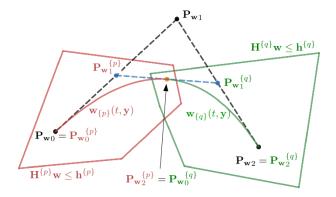

Fig. 5: Example of curve decomposition with the De Casteljau algorithm. The original curve comprises 3 control points (black). It is decomposed into two curves comprising the same number of control points each (3). We can then constrain the control points of the first curve (red) to lie in the first set of constraints, and similarly constrain the control points of the second curve (green) to lie in the second set of constraints. As a result, if the constraints can be satisfied, the connecting control point of both curves satisfies both set of constraints, and we obtain the guarantee that each sub-curve satisfies its respective set of constraints. Interestingly, the control points of the sub-curves are constrained to belong to their respective cones, but those of the original curve can lie outside of the constraints.

Finally the constraints of (13) can be rewritten to deal with the contact switches. The kinematic constraints expressed at each control points are written:

$$\underbrace{\mathbf{K}^{\{z\}}\mathbf{P}_{i}^{y\{z\}}}_{\mathbf{A}_{i}^{\{z\}}}\mathbf{y} \leq \underbrace{\mathbf{k}^{\{z\}} + \mathbf{K}^{\{z\}}\mathbf{P}_{i}^{s\{z\}}}_{\mathbf{a}_{i}^{\{z\}}}, \forall i, \forall z \in \{p, q\}$$
(19)

and the dynamic constraints:

$$\underbrace{(\mathbf{H}^{\{z\}}\mathbf{P}_{\mathbf{w}j}^{y\{z\}}}_{\mathbf{D}_{j}^{\{z\}}}\mathbf{y} \leq \underbrace{\mathbf{h}^{\{z\}} - \mathbf{H}^{\{z\}}\mathbf{P}_{\mathbf{w}j}^{s\{z\}}}_{\mathbf{d}_{j}^{\{z\}}}, \qquad (20)$$
$$\forall j, \forall z \in \{p, q\}$$

⁵⁰¹ We can then stack the constraints:

$$\mathbf{A} = \begin{bmatrix} \mathbf{A}_{0}^{\{p\}} \\ \vdots \\ \mathbf{A}_{n}^{\{p\}} \\ \mathbf{A}_{0}^{\{q\}} \\ \vdots \\ \mathbf{A}_{n}^{\{q\}} \end{bmatrix} \mathbf{a} = \begin{bmatrix} \mathbf{a}_{0}^{\{p\}} \\ \vdots \\ \mathbf{a}_{n}^{\{q\}} \\ \mathbf{a}_{0}^{\{q\}} \\ \vdots \\ \mathbf{a}_{n}^{\{q\}} \end{bmatrix} \mathbf{D} = \begin{bmatrix} \mathbf{D}_{0}^{\{p\}} \\ \vdots \\ \mathbf{D}_{2n-3}^{\{p\}} \\ \mathbf{D}_{0}^{\{q\}} \\ \vdots \\ \mathbf{D}_{2n-3}^{\{q\}} \end{bmatrix} \mathbf{d} = \begin{bmatrix} \mathbf{d}_{0}^{\{p\}} \\ \vdots \\ \mathbf{d}_{2n-3}^{\{p\}} \\ \mathbf{d}_{0}^{\{q\}} \\ \vdots \\ \mathbf{d}_{0}^{\{q\}} \\ \vdots \\ \mathbf{d}_{2n-3}^{\{q\}} \end{bmatrix}$$
(21)

We recall that in our case n = 6. Finally, we can rewrite FP (13) with a contact switch as:

$$\begin{array}{ll} \mbox{find} & \mathbf{y} \\ \mbox{s. t.} & \mbox{A}\mathbf{y} \leq \mathbf{a} \\ & \mbox{D}\mathbf{y} \leq \mathbf{d} \end{array}$$

This boils down to check if each control point of each split curve satisfies the constraints of the current contact phase. 504

E. General case

In the general case, the same idea will apply. In the contin-507 uous case, we use the De Casteljau algorithm to split c(t) into 508 as many curves as required, thus falling back to a formulation 509 with no contact switches. In the discrete case, we assign 510 the appropriate constraints for each discretized time step. 511 While these decompositions appear mathematically heavy, 512 from a programming point of view, they can be automatically 513 generated, and thus are in fact simple to implement. 514

In our experiments, we only consider three consecutive phases (which correspond to one step), and solve a new problem for each subsequent set of phases. We call one such convex problem "*CROC*", which stands for *Convex Resolution Of Centroidal dynamic trajectories.* 519

F. Non-conservative continuous formulation

The presented continuous formulation is more conservative than the discretized one. Constraining the control points to lie inside the constraint set prevents from the generation of curves such as the one illustrated in Figure 6.

However, by relying on the De Casteljau algorithm, it is 525 possible to continuously satisfy the constraints while consid-526 ering control points outside of the constraint set. Indeed when 527 a curve is split, the constraints no longer apply to the control 528 points of the original curve, but to the control points of the 529 sub-curves. This is illustrated in Figure 5. If the curve is split 530 an infinite number of times, it is straightforward to see that 531 the original curve can span entirely its original definition set 532 as the position of the control points converge to the original 533 curve as the number of split increase. 534

The price to pay is that the number of constraints increases with the number of curve splittings: a curve of degree s split b times comprises (s + 1) * (b + 1) constraints. The higher the number of splits is, more the number of constraints to address increases. A parallel can be made with the discretized approach: the lower the discretization step is, the higher the number of constraints is.

We believe that a deeper analysis of the pros and cons of 542 using a continuous formulation, not only in the case of CROC, 543 but with any other formulation of the problem, requires a 544 significant amount of research, and thus will be discussed in 545 a future work. In this paper, we only divide the curve at the 546 transition points, and we show in our experiments that this 547 is already sufficient to perform similarly to the discretized 548 approaches, while ensuring comparable time performances. 549

G. Cost function and additional constraints

As the transition feasibility problem is addressed by CROC, 551 a feasible COM trajectory is computed. It is possible to 552

506

520

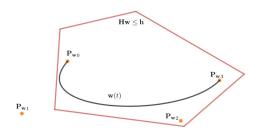

Fig. 6: The curve $\mathbf{w}(t)$ belongs entirely to the convex boundaries (red), while a control point $\mathbf{P}_{\mathbf{w}1}$ lies outside of them.

optimize this trajectory to minimize a given cost function $l(\mathbf{y})$, 553 either linear or quadratic. In the latter case the FP problem (22) 554 then becomes a Quadratic Program (QP). One can for instance 555 minimize the integral of the squared acceleration norm or the 556 angular momentum. This cost function is irrelevant to solve 557 the transition feasibility problem, but it can be later used as a 558 reference COM trajectory for a whole-body motion generator, 559 or as an initial guess for a nonlinear solver as discussed in 560 Section IV-F. 561

The formulation also allows to add inequality constraints on c and any of its derivatives by rewriting the expression of the control points of the desired curve as done in equation (17). Here again, these constraints can either be verified continuously on the concerned control points, or in a discretized fashion. In any case, they take the form:

$$\mathbf{O}\mathbf{y} \le \mathbf{o}$$
 (23)

We use such constraints to impose bounds on the velocity and acceleration of the center of mass or on the angular momentum variation. The most generic form of our continuous problem is thus the following QP:

$$\begin{array}{ll} {\rm find} & {\bf y} \\ {\bf min} & l({\bf y}) \\ {\bf s.\,t.} & {\bf Ay} \leq {\bf a} \\ & {\bf Dy} \leq {\bf d} \\ & {\bf Oy} \leq {\bf o} \end{array}$$

In our experiments we set constraints on the acceleration and velocity and minimize the squared acceleration norm as a cost *l*. In the remainder of the paper "*CROC*" refers to this generic QP. If nothing is specified, by default *CROC* refers to the continuous formulation and with the inequalities representation of the dynamic constraints, as in the QP (24).

578 H. Time sampling

In the previous sections, in order to remain convex when computing $\mathbf{w}(t)$ (equation (6)) we assumed that the duration of each phase $T^{\{p\}}, T^{\{p+1\}}$ and $T^{\{p+2\}}$ was given.

Time can be reintroduced in the problem using a bi-level optimization approach [36]. However, in this work we choose a more pragmatic offline-sampling approach to compute relevant timing candidates, which turns out to be lossless among all of our experiment set. To achieve this, we consider a large variety of instances of the transition problem. We first consider all the scenarios demonstrated in Section VI (for HRP-2 and HyQ), from which we extract instances of the transition problem. We secondly generate random scenarios (Figure 9). We randomly allocate initial and end velocities for the center of mass along the direction of motion, between 0 and 1.5 $m.s^{-1}$.

For a total of 10 000 instances of the transition problem, we 594 sample various combinations of times, solve the corresponding 595 OPs and check whether a solution is found. In theory, this 596 would mean that we need to sample an infinity of time com-597 binations in order to be complete. However, we pragmatically 598 reduce this number and give up on the completeness while 599 maintaining a high success rate as follows: we sampled a time 600 for each duration phase $T^{\{z\}}$ by choosing a value between 601 0.1 and 2 seconds for phases without end-effector motion 602 and between 0.5 and 2 seconds for phases with end-effector 603 motion, with increments of 50ms. For a sequence of three 604 phases with one phase with end-effector motion, this gives a 605 total of 43320 possible combinations. We tested CROC with all 606 these combinations on various problems : with HRP-2 or HyQ 607 robots on flat and non-coplanar surfaces, for several thousands 608 of states. 609

Upon analysis of the results of the convergence of the 610 OPs, we found out that we can use a small list of timings 611 combinations (5 in our case, shown in table I) that covers 612 100% of the success cases for all the robots and scenarios 613 tested. We thus solve a maximum of 5 QPs for each validation. 614 Figure 7 shows the evolution of the success rate according to 615 the number of timings combinations used. We observe that 3 616 combinations are enough to reach 99% of success but that two 617 additional combinations are required to reach exactly 100%. 618

The number 100% may appear large. Intuitively however, it 619 seems to highlight the fact that the accuracy of the transition 620 times are not that important for the considered feasibility 621 problem. Indeed $T^{\{p\}}$ constrains the COM trajectory to lie 622 in the intersection of two contact phase constraints at this 623 precise time. However this intersection is in general of a 624 significant volume. As a result the COM trajectory will belong 625 to the intersection for a large time window, which results in a 626 significant slack in the selection of time. 627

We recall that here, we are only concerned in finding 628 feasible times. For instance, typical double support times when 629 walking on flat ground are closer to 0.2 seconds than 1 second 630 for $T^{\{\bar{p}\}}$ in dynamical cases. However 0.2 seconds is not 631 feasible when starting from a null velocity. In both cases the 632 interval between 0.8 and 1.2 seconds is almost always feasible 633 in our experiments, which explains why such timings were 634 selected for $T^{\{p\}}$. As such, table I should **not** be considered 635 as a table giving optimal contact time durations, but rather one 636 maximizing feasibility over our set of problems. 637

IV. PERFORMANCES OF CROC

A. CROC vs a nonlinear solver

Computing the success rate of our method is a hard task because we do not have any way to determine the "ground truth" feasibility of a transition (ie. there does not exist any 642

	$\begin{array}{c c} \text{timings (s)} \\ T^{\{p\}} \mid T^{\{p+1\}} \mid T^{\{p+2\}} \end{array}$		Success rate (%)	
ł	1	0.8	0.8	91.2
	1	0.75	0.9	89.2
	0.8	0.8	0.9	88.3
	0.7	0.5	0.85	77.7
	1.2	0.6	1.1	70.8

TABLE I: Success rate with the five used timings combinations.

method able to determine in finite time whether there exists a
valid centroidal trajectory between the two states). We choose
to compare the relative success rate of CROC with respect to
a state-of-the-art non-linear formulation of the same problem
[18], which is reported to give similar results to the one from
Ponton et al. [22].

Both approaches share similar formulations in terms of kinematic constraints. Conversely the nonlinear solver does not use the conservative formulation of CROC that makes the problem convex, and thus is able to explore a larger part of the solution space, and thus to find a "more optimal" solution of a given locomotion problem.

From a practical point of view, the nonlinear solver is also 655 able to tackle motion synthesis problems over large sequences 656 of contacts. While CROC only interpolates trajectories over 657 two waypoints given by the planner, the non-linear solver 658 is able to ignore the waypoints to find a better solution 659 (Figure 8). This locality is, in our experience, the main source 660 of difference between the trajectories computed by CROC 661 and the nonlinear solver. This difference is what ultimately 662 motivates the use of the nonlinear solver to refine the trajec-663 tories obtained by CROC in Section V-C, at a stage where 664 the contact sequence is fixed and the combinatorial is not a 665 problem anymore. 666

667 B. Comparison benchmarks

The scenarios used in our benchmarks consist of randomly generated sequences of 3 contact phases such that:

- both initial and final contact phases are in static equilibrium
- both initial and final contact phases have the same effectors in contact, between two and four

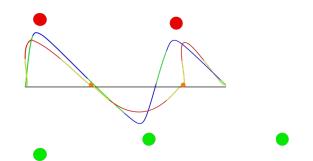

Fig. 8: Example of centroidal trajectories generated with CROC and a nonlinear solver (bird eye view), in a case of bipedal walking. The red and green circles represent the contact positions of the (respectively) left and right feet centers over time. The red and yellow (respectively related to single and double support phases) curve is the curve obtained through the concatenation of curves computed with CROC. The blue and green (respectively related to single and double support phases) curve is obtained through optimization of the latter curve with a nonlinear solver. The orange circles represent the constrained COM positions resulting from the contact planning phase, which are ignored by the nonlinear solver to produce smoother motions.

- there is exactly one contact repositioning between both initial and final contact phases and no other contact variation

- the intermediate contact phase is not required to be in static equilibrium.

These benchmarks thus only consider the case of a "repositioning" of an end-effector but as explained in section III-E this is our main use case for CROC as it encompasses the only two other possible cases (creating a contact or breaking a contact) and because this is the kind of contact sequences produced by our contact-planner.

For this benchmark we considered two kind of scenarios. In the first case, we only sample contact phases with coplanar contacts. In the second case, we sample truly random contacts, which lead to contact phases with non-coplanar contacts and contact sequences that require complex motions. Some examples of randomly generated scenarios are shown in Figure 9.

All the benchmarks were run on a single core of an Intel Xeon CPU E5-1630 v3 at 3.7Ghz. The QP problems are solved with QuadProg, and the FP problems with GLPK [37].

The first benchmark compares four different methods: both 695 discrete³ and continuous formulation of CROC presented in 696 this paper (using the inequality representation of the con-697 straints), the nonlinear resolution proposed in [18] and the 698 same nonlinear method but initialized with the solution found 699 by CROC when available. As we compare the relative success 700 rate between the methods, we only consider the scenarios 701 where at least one of the method finds a solution when 702 computing the percentage of success. The results are shown 703 in table II. 704

³with 7 discretization points per contact phases, which corresponds to a time step of approximately 100ms.

677

678

692

693

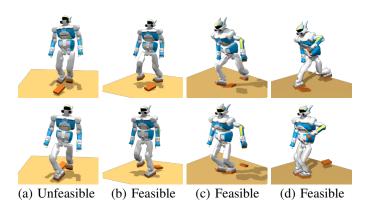

Fig. 9: Examples of random contact transitions used for benchmarking. Top row : initial configuration, bottom row : final configuration. (a) and (b) only have both feet in contact, (c) and (d) have both feet and the left hand in contact. All the displayed configurations are in static equilibrium, but the intermediate configuration with one less contact (not shown) is not constrained to be in static equilibrium. None of the methods found a solution for the transition (a), the other transitions were successfully solved.

Method	Coplanar success (%)	Non-coplanar success (%)	Total time (ms)
CROC (discrete)	89.7	60.6	3.89
CROC (continuous)	88.4	57.2	3.93
Non-linear	100	94.1	$\simeq 150$
N-L with init guess	100	100	$\simeq 130$

TABLE II: Comparison between CROC and a non linear solver for randomly generated contact sequences of three contact phases. The two first methods are the ones presented in this paper, with either the discrete³ or continuous formulation and using the inequality representation of the dynamic constraints. These methods are compared with the non linear solver presented in [18], either with their naive initial guess (Nonlinear) or with the solution found by CROC as an initial guess when available (N-L with init guess). The percentages on the "success" columns only consider the scenario where at least one method found a solution.

705 C. How conservative is CROC?

Because of its conservative reformulation, CROC does not 706 cover the whole solution space. As expected, our method 707 finds less solutions than the nonlinear solver. In the coplanar 708 case, CROC almost finds 90% of the solutions. In the non-709 coplanar case, the centroidal trajectory may be required to 710 present several inflexion points and/or to be really close of 711 the constraints, which cannot be represented using a single 712 variable control point for the trajectory. This explains the 713 difference of success rates between the two cases. However, 714 even in such complex cases CROC still finds around 60% of 715 the solutions. 716

717 D. Computation time

As claimed in the introduction, CROC is about two order of magnitude faster than the nonlinear solver that we are using for the centroidal motion generation. Thanks to this efficiency, ⁷²⁰ it is realistic to use our method during the contact planning to ⁷²¹ evaluate hundreds of candidate transitions. ⁷²²

For the inequality representation with the double description 723 method, the computation time allocated to solve the QP 724 of equation (24) is extremely fast with $50\mu s$ on average. 725 The computation time of CROC, which comprises the time 726 required to solve the OP and the time required to compute 727 all the constraints matrices of equation (21) is around $400\mu s$. 728 The total time in table II also includes the time required 729 by the double description method. However, in some cases 730 the same contact phases may be used several times and the 731 double description method only needs to be computed once per 732 contact phase, thus the time required for the double description 733 may be factorized. 734

1) Comparison with the equality representation: Table III shows the difference in computation time between the inequality and equality formulation, with a varying number of contacts.

Formulation	Metric	Number of contacts		ntacts
		2	3	4
Double-	DD time (ms)	3.52	14.88	28.16
Description	Total time (ms)	3.93	16.18	37.41
Force	Total time (ms)	13.01	25.28	49.65

TABLE III: Comparison between the computation times required to generate and solve the FP⁴ defined by CROC using either the Double Description (DD) or the Force formulation.

The major difference between the two representations lies 739 in the dimension of the variables and the constraints of the 740 problem, which is greater in the case of the force formulation. 741 As shown in Table III the computation times between the 742 double description and the force formulations remain in the 743 same order of magnitude for 2 to 4 contacts, with an advantage 744 for the double description. However this advantage reduces as 745 the number of contacts increase. Indeed, while the computation 746 time for the force formulation doubles at each additional 747 contact, the time grows cubicly with the Double Description 748 (DD) formulation. 749

E. Comparing the continuous and discretized formulations

The results of Table II confirm that the continuous formu-751 lation presented in section III-C2 is conservative with respect 752 to the discrete formulation. However, these results show only 753 a marginal difference of success rate between the discrete and 754 continuous formulation of CROC (1 - 4%). This can first be 755 explained by the fact that the De Casteljau decomposition 756 allows for the control point y to lie outside of the constraints 757 (Figure 5), thus making the method less restrictive. We propose 758 a second explanation, which is only intuitive (thus not a claim): 759 the remaining missing solutions are necessarily those that will 760 result in the curve lying close to the constraint boundaries. 761 The discretized approach will theoretically find them, but 762

 4 QP and FP give similar times for the DD formulation, while the FP is much more efficient in the Force formulation. This is only an implementation problem, since GLPK exploits the sparsity of the problem while QuadProg does not.

735

736

737

738

⁷⁶³ the chances of finding a trajectory partially outside of the ⁷⁶⁴ constraint sets are much higher in this case (Figure 3).

Moreover, in section III-D2 we proposed to only split the trajectory in one curve for each contact phases but it is possible to split the trajectory in an arbitrary number of curves, as long as each curve is entirely contained in one contact phases, as detailed in section III-F. By increasing the number of split curves, we can further reduce the loss of solutions.

1) Invalid solutions of the discretized methods: Again, the major drawback of a discretized approach is that the portions of the curve in-between two discretization points are never checked and could violate the constraints (Figure 3).

In order to measure this risk four variants of CROC were 775 compared with the same randomly generated contact sequence 776 as before: the discretized version with three different values of 777 number of discretization points per phases and the continuous 778 version presented in this paper. The four variants use the 779 inequality representation of the dynamic constraints. Then, for 780 each centroidal trajectory found as a solution, the dynamic 781 constraints were verified with a really small discretization step. 782 If the constraints were not satisfied for at least one point of 783 the trajectory, we count this solution as "invalid". 784

Method	Invalid s	Computation	
Wiethou	Coplanar	Non-coplanar	time (ms)
Discrete (3 pts)	10.6	19.7	0.20
Discrete (7 pts)	6.7	9.3	0.37
Discrete (15 pts)	4.2	6.9	0.75
Continuous	0	0	0.41

TABLE IV: Comparison between the method CROC with the discrete formulation (D), with varying number of discretization points, and the continuous formulation (C) presented in this paper.

Table IV shows that the percentage of invalid solutions 785 found by the discrete methods is non negligible. Obviously, 786 as the number of discretization points increase this percentage 787 decreases. As shown in equation (11) the number of constraints 788 in the discretized LP problem is proportional to the number of 789 discretization points. Thus the number of discretization points 790 used is a complex parameter to tune, as it is a compromise 791 between the computation time and the risk of finding invalid 792 solutions. This issue is common to all methods that rely on 793 discretization. It emphasizes the fact that we need a continuous 794 method, able to check exactly whether the whole trajectory is 795 valid with a fixed number of constraints in the problem. 796

2) Computational advantage of the continuous formulation:
Depending on the discretization, the continuous formulation
can be slower or faster to compute. However, to reach less
than 5 % of false positive trajectories with the discretized
approach, table IV shows that the continuous formulation is
actually faster.

⁸⁰³ F. Using CROC to initialize a non linear solver

Choosing an initial guess for the nonlinear solver of a trajectory generation method is essential but may be challenging for multi-contact motions. The quality of this initial guess has a significant influence on the convergence of the nonlinear solver. For the nonlinear method considered in this section [18] proposed a naive initial guess of the centroidal trajectory based solely on the position of the contact points. 810

Interestingly, Table II suggests that the solution set spanned 811 by CROC is not strictly included in the one spanned by 812 this nonlinear solver with this naive initial guess. Using the 813 solution of CROC to initialize the nonlinear solver can thus 814 help it to converge and increase its success rate. As shown 815 in Table II, this improvement only appears for the non-816 coplanar case because the naive initial guess used is always 817 close to a valid solution in the coplanar case. We expect that 818 the importance of the initial guess will grow if the contact 819 sequences do not allow static equilibrium configurations at the 820 contact phases, and will check this hypothesis in the future. 821

Moreover, by using the solution of CROC to initialize the nonlinear solver we measured a reduction of the number of iterations required to converge of 20% on average, reducing the total computation time (ie. it is faster to use CROC and then the non-linear solver than using the non-linear solver directly).

G. Validity of our kinematic constraints

As explained in the section II-C, our representation of 829 the kinematics constraints is a necessary but not sufficient 830 approximation. In order to evaluate the accuracy of this 831 approximation, for each feasible transition found by CROC 832 between random configurations, we tested explicitly the kine-833 matic feasibility of the centroidal trajectory with an inverse 834 kinematic. This tests showed that 17.5 % of the trajectories 835 found by CROC were not kinematically valid. This shows 836 that our approximation of the kinematic constraints is not 837 sufficient. However, this is not a limitation of CROC, but rather 838 of the formulation of the kinematic constraints, which we hope 839 to improve in the future. 840

Moreover, by doing the same tests without any kinematic constraints we found a total of 72.3 % of kinematically unfeasible trajectories. This results show the interest of our kinematic constraints approximation to improve the feasibility of the trajectories found by CROC.

V. EXPERIMENTAL FRAMEWORK

Figure 10 shows the complete framework used for our 847 experiments, implemented with the Humanoid Path Planner 848 [38] framework. The inputs are an initial (respectively goal) 849 position and orientation for the root of the robot, as well as 850 a set of bounds on the velocities and acceleration applying to 851 the COM and the end-effector, and a complete representation 852 of the 3D environment. The output is a dynamically consistent 853 and collision free whole-body motion which can be played on 854 a real robot as shown in section VI. 855

In this paper, we modify the contact generation method by adding CROC as a feasibility criterion, and connect all the pieces of the framework together. These other pieces are used as black boxes and thus only briefly introduced, with a reference to their respective publications.

828

12

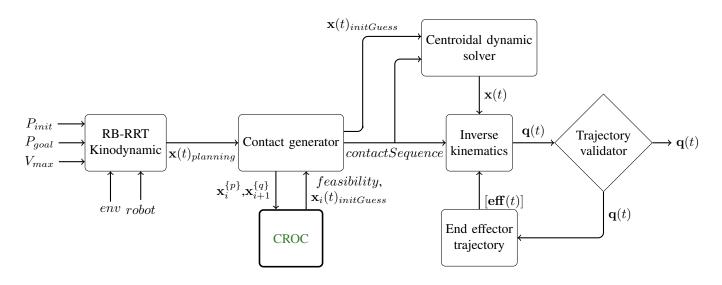

Fig. 10: Complete experimental framework.

A. RB-RRT kinodynamic planner 861

The first block generates a rough guide trajectory⁵ for the 862 root of the robot $\mathbf{x}(t)_{planning}$. It thus solves the sub-problem 863 \mathcal{P}_1 defined in Figure 2. RB-RRT is a planning method based 864 on the sampling-based RRT algorithm, which plans a guide 865 trajectory for the geometric center of a simplified model of 866 the robot. It thus solves a problem of lower dimension than 867 planning in the configuration space of the real robot. The 868 goal of this method is to find a trajectory for the root of the 869 robot which will allow contact creation. This block was first 870 presented in [15] and later extended to a kinodynamic version 871 in [16], which is the one we use. 872

B. Contact generator with CROC as a feasibility criterion 873

The contact generator block computes a contact sequence, 874 as a list of whole body postures along the discretized guide 875 trajectory $\mathbf{x}(t)_{planning}$. This block solves the sub-problem \mathcal{P}_2 876 defined in Figure 2. It also generates an initial guess of the 877 timing of each contact phase. This method was also introduced 878 in [15]. 879

CROC is used as a feasibility criterion by this contact 880 generator. More precisely it is used as a filter to determine 881 which transitions are unfeasible and discard them during the 882 planning in order to produce contact sequence containing only 883 feasible transitions. CROC will thus be called for each contact 884 transitions considered by the contact generator $(\mathbf{x}_i^{\{p\}} \text{ and } \mathbf{x}_{i+1}^{\{q\}})$ 885 in Figure 10) and output the feasibility of the given contact 886 transition. The integration of CROC to this pipeline provides 887 strong guarantees that the computed contact sequence will 888 lead to a feasible CoM trajectory and thus that the centroïdal 889 dynamics solver will converge with this contact sequence as 890 input. 891

A byproduct of the feasibility test made with CROC is a 892 feasible CoM trajectory between each adjacent contact phases 893 $(\mathbf{x}(t)_{initGuess})$. This trajectory, not optimal, is used as an 894

initial guess for a non-linear solver which will use it to 895 compute an optimal trajectory.

C. Centroidal dynamics solver

The *centroidal dynamics solver* block was proposed in [18], 898 it takes as input the contact sequence found by the previous 899 block, along with an initial guess of the timing of each phases 900 and an initial guess of the CoM trajectory. The output of this 901 block is a CoM trajectory that respects the centroïdal dynamics 902 of the robot $\mathbf{x}(t)$ and minimizes a tailored cost function. This 903 method solves an optimal control problem with a multiple-904 shooting algorithm implemented in MUSCOD-II [39]. 905

The main interest of using a non-linear solver with the input 906 of CROC is that the trajectory can then be refined globally 907 (while the authors advise to use CROC with at most 3 contact 908 phases), at the cost of a higher computational burden. CROC 909 and the non linear solver are thus complementary: CROC 910 does not provide an optimum, but is computationally efficient, 911 which allows it to be used with a trial-and-error approach (ie. 912 trying to solve problems that we dont know if a solution exist, 913 until we find a solvable problem). Conversely, the non-linear 914 solver is too computationally expensive to be used with a trial-915 and-error approach, but will in general propose a trajectory 916 with a better optimum with respect to the optimized cost 917 function. The proposed framework is designed to call this non-918 linear solver only once, with a problem that is known to have 919 a solution. 920

The three different trajectories found in the framework of 921 Figure 10 are shown in Figure 8, $\mathbf{x}(t)_{planning}$ is represented 922 in black, $\mathbf{x}(t)_{initGuess}$ in yellow and orange and $\mathbf{x}(t)$ in green and blue. This figure shows a trajectory computed with CROC 924 and the same trajectory refined with a non-linear solver as an 925 illustration of the typical differences of both approaches. 926

D. Inverse kinematics

The whole-body motion q(t) is generated with a second 928 order Inverse Kinematics solver, similar to [40]. This method 929

923

927

takes as input a reference trajectory for the CoM, as well as references for the trajectories of the end-effectors.

932 E. End-effector trajectory

In order to automatically generate valid end-effector tra-933 jectories for complex and constrained scenarios, we use a 934 dedicated block. The trajectories computed are such that 935 the whole limb is collision free and respect the kinematic 936 constraints. The trajectories are represented as Bezier curves 937 constrained to have a null initial and final velocity, acceleration 938 and jerk and which respect velocity, acceleration and jerk 939 bounds along the whole trajectory. In order to guarantee that 940 the whole surface of the effector creates or breaks the contact 941 at the same instant the curves are also constrained to have a 942 velocity orthogonal to the contact surface for a small time step 943 at the beginning and the end of the trajectory. 944

The positions of the control points of this Bezier curve 945 are computed as the solution of a QP optimization method, 946 using a cost function that defines a compromise between a 947 reference optimal trajectory and a collision free one, provided by a probabilistic planner. This planner computes a geometric 949 path for the moving limb that respects all the kinematic and 950 collision constraints. However it may present discontinuities 951 in velocity and higher derivatives and does not respect the 952 dynamic constraints described in the previous paragraph. 953 954 Moreover, as with any sampling-based method this path will not be optimal. Because of this, this geometric path will not 955 be used directly as the end-effector trajectory but will be used 956 inside the cost function of our optimization method. 957

Then several iterations are made between this optimization method and the inverse kinematics method, producing trajectories for the end-effectors and checking if the resulting wholebody motion is valid. If not, the weight of the cost associated to the solution of the geometric planner is increased at each iteration, until a valid motion is found.

964

VI. EXPERIMENTAL RESULTS

965 A. Experimental scenario

The complete experimental framework presented in the 966 previous section was tested on several locomotion scenarios in 967 semi structured environments, each scenario showing specific 968 features or difficulties. We insist that the only manual inputs 969 given to our framework were an initial and a goal position 970 for the root of the robot. Most of the obtained motions are 971 demonstrated in the companion video. They were validated 972 either in a dynamics simulator or on the real robot. 973

1) Inclined platform crossing: This scenario requires the 974 robot to go from one flat platform to the other by taking a step 975 on an inclined platform (Figure 12). The scenario is designed 976 such that no quasi-static solution exists to the problem, and is 977 truly multi-contact for two reasons: firstly part of the motion 978 occurs entirely on non-flat ground; secondly the problem is 979 unfeasible if the right foot is the one selected to go first on the 980 platform. CROC then allows to invalidate unfeasible contact 981 sequences that would involve directly taking a step on the final 982 platform, or take a step with the right foot first (Figure 13). It 983 rather allows to find a solution where the left foot is used to 984

Fig. 12: Platform crossing scenario: no quasi-static solution exists for the flying phase where the left foot is on the inclined platform.

step on the inclined platform (Figure 12). A feasible wholebody motion is demonstrated in the companion video.

Additionally, CROC also ensures that the left foot is positioned in such a way that the problem becomes feasible, which is not trivial considering the size of the solution space for the chosen step position (Figure 19(a)). 987

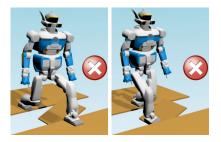

Fig. 13: Unfeasible stepping strategies invalidated by CROC.

2) 10 cm high steps: This experimental setup is an industrial set of stairs shown in Figure 11 and 18(a). It consists of six 10 cm high and 30 cm long steps. This experiment was done with the HRP-2 robot. All the valid contact sequences produced contain at least 13 contact phases as the robot is kinematically constrained to put both feet on each step.

The complete motion is shown in the companion video. The crouching walk seen is required to avoid singularities in the knee of the extending leg, which are not tolerated by the lowlevel controller.

An example of unfeasible contact sequence filtered out by our feasibility criterion is depicted on Figure 14. All three configurations in this sequence are valid (ie. respect kinematics and dynamics constraints) but there isn't any valid centroidal trajectory between the last two configurations. Our feasibility criterion will filter out this kind of contact transitions during contact planning.

3) 15 cm high steps with handrail: This other set of stairs 1008 is composed of four 15 cm high steps and equipped with 1009 a handrail. The contact sequence is shown in Figure 18(b) 1010 and snapshots of the motion are shown in Figure 15. This is 1011 a typical multi-contact problem, showing an acyclic contact 1012 sequence with non co-planar contact surfaces. The problem 1013 was already solved in a previous work [17], but the input 1014 contact sequence and effector trajectories had to be manually 1015 selected from a large number of trials. In this paper, the only 1016 input is a root goal position at the top of the stairs. 1017

Fig. 11: Snapshots of the motion for the 10cm stairs, the complete motion is shown in the companion video.

Fig. 14: Exemple of unfeasible contact transition detected by CROC and rejected during contact planning

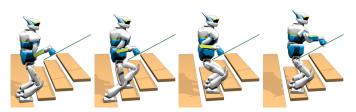

Fig. 15: A feasible multi-contact sequence for a stair climbing with handrail support on the HRP-2 robot automatically computed with our contact planner and CROC.

¹⁰¹⁸ A example of centroidal trajectory found by CROC for one ¹⁰¹⁹ contact transition in this scenario is shown in Figure 19(b).

4) Flat surface with ground level obstacles: This exper-1020 imental setup consists of a flat floor with obstacles, shown 1021 in Figure 18(c) and (d). In (c) there is only one obstacle 1022 in front of the robot's initial position, in (d) we add smaller 1023 obstacles on the floor. This scenario shows that our planner 1024 is able to compute a valid guide root trajectory that avoids 1025 bigger obstacles and that our contact planner is able to avoid 1026 collision with smaller obstacles on the ground. 1027

The difficulty of this scenario lies on the generation of collision free feet trajectories. Indeed, some obstacles are small enough to permit the feet to pass over the obstacles, but others are too high and require a lateral motion of the feet to avoid them. As shown in Figure 16 our method presented briefly in section V-E is able to find such trajectories automatically.

5) Uneven platforms: This setup consists of 30 cm long 1034 and 20 cm wide platforms, oriented of 15° around either the x 1035 or y axis. This scenario is particularly difficult for the contact 1036 planner because of all the possible collisions generated by the 1037 feet. We recall that the feet of HRP-2 are 24 cm long for 14 1038 cm wide, which means that the platforms of this setup are only 1039 a few centimeters bigger than the feet of the robot. Because of 1040 this, there is really few collision free candidates positions for 1041

Fig. 16: Feet trajectories computed for scenario with ground level obstacles. Green for right foot and red for left foot.

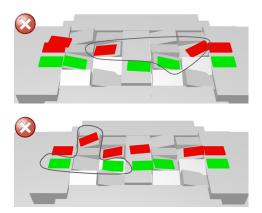

Fig. 17: Examples of unfeasible contact sequences filtered out by CROC. There doesn't exist any valid centroidal trajectory for the contact transitions encircled in black.

the feet. The probability of finding a contact position which 1042 leads to a collision-free configuration while maintaining the 1043 equilibrium is extremely small for this setup. 1044

The contact sequence found is shown in Figure 18(e), 1045 snapshots of the motion are shown in Figure 1 and a motion for 1046 this scenario is shown in the companion video. These motions 1047 have been validated on the real robot. 1048

The Figure 17 shows two examples of unfeasible contact 1049 sequence filtered out by CROC in this scenario.

6) *Quadrupedal between inclined planes:* The quadrupedal 1051 robot HyQ navigates between two planes inclined at 45°. 1052 Figure 19(c) shows the the centroidal trajectory found by 1053 CROC in this scenario for one contact transition. This scenario 1054 shows that our method may be adapted to any type of legged 1055 robot. 1056

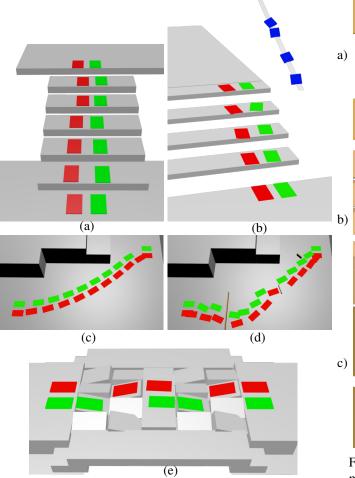

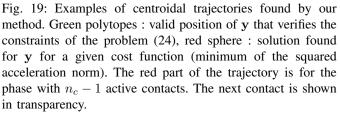

Fig. 18: Examples of contact sequences found with our framework. The color patches represent the planned contact location: green for right foot, red for left foot, blue for right hand.

1057 B. Benchmarks

1) Using CROC as a feasibility criterion: In order to 1058 quantify the improvement of our contact planner from the use 1059 of CROC as a feasibility criterion, we used the following test 1060 procedure: for some of the scenarios presented in the previous 1061 section, we tried to solve the problem using our framework 1062 with and without using CROC as a feasibility criterion during 1063 the contact planning. We then measured the success rate of 1064 the centroidal dynamic solver with the contact plan found. 1065 The results are shown in Table V. 1066

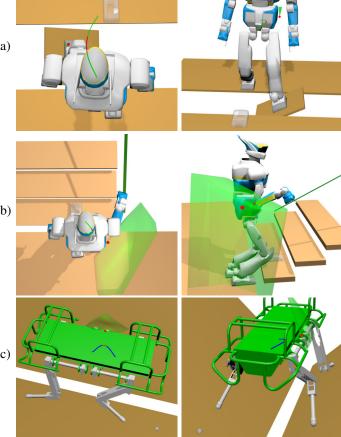

In the walking on flat floor scenario, CROC brings only 1067 a marginal improvement to our contact planner because our 1068 previously used heuristics were sufficient in this case to 1069 provide a feasible contact plan most of the time. However, in 1070 all the other cases the results empirically prove the main claim 1071 of this paper: using CROC as a feasibility criterion during the 1072 contact generation greatly increases the success rate of the 1073 centroidal trajectory generation because it produces contact 1074 plans with only feasible transitions. Another expected result 1075 is that there isn't any "false positive" found by our method: 1076 when CROC converges, the non linear solver always converges 1077

for the same transition.

The trade-off is an increase of the computation time required 1079 by the contact generator, from a few percents to nearly the 1080 double. This is explained partly by the addition of the time 1081 required to run CROC for each candidates, but mostly by the 1082 fact than we need to evaluate a lot more candidates before 1083 we find a valid one (ie. which lead to a feasible transition). 1084 This is shown in the column 4 of Table V, which provides 1085 the average number of contact candidates evaluated during the 1086 contact planning phase. Actually, depending on the scenario 1087 considered, only 7 to 16% of the total "contact planning" 1088 computation time is spent solving CROC problems. The rest of 1089 the time is mostly spent by projection methods and collision 1090 tests. This shows that our formulation is fast enough to be 1091 used inside a contact planner, without too much impact on its 1092 computation time. 1093

2) Benchmarks of the complete framework: Table VI shows a benchmark of the performances of the complete motion planning framework presented in section V. We recall that this framework take as input only an initial and goal position 1097

		Contact planning		Centroidal
Scenario	Method	time (s)	Evaluated candidates (avg.)	dynamic solver success (%)
Walk	Without CROC	0.58	8.2	98
(flat)	With CROC	0.63	21.9	100
Stairs	Without CROC	0.61	24.4	52
(3 steps)	With CROC	0.87	92.9	100
Stairs	Without CROC	1.26	147.2	31
(handrail)	With CROC	1.87	384.0	100
Uneven	Without CROC	3.91	679.1	15
platforms	With CROC	7.59	3030	100

TABLE V: Evaluation of the feasibility of the contact plans found with or without CROC as a feasibility criterion. The *Contact Planning* column shows the computation time required by the contact planning phase and the average number of contact candidates evaluated during this phase. The last column shows the success rate of the centroidal trajectory generation method with the contact sequence found by the planner. Each scenario have been run 100 times.

¹⁰⁹⁸ for the center of the robot and produce as output a whole body ¹⁰⁹⁹ motion.

Scenario	Motion	Total	Success
Scenario	duration (s)	time (s)	(%)
Walk (3 steps)	7.7	4.43	100
Walk with obstacles	55.02	51.5	99.3
Stairs	16.23	12.56	90.5
Stairs with handrail	23.13	18.09	88.05
Uneven platforms	14.94	17.83	83.5

TABLE VI: Performance analysis of the complete motion planning framework presented in section V, without the time required to compute collision free end-effector trajectory. *Motion duration* is the average duration of the solution, *total time* is the average computation time required to compute the motion. *Success* is the success rate of the complete framework.

We observe that the success rate is close to 100% except 1100 for complex scenarios where it is still above 80% in the worst 1101 case. The main cause of failure in our current implemen-1102 tation of the framework is the inverse kinematics that may 1103 produce whole-body motions that do not respect the kine-1104 matic constraints or that are in self-collision. Concerning the 1105 computation time, in most of the cases we achieve interactive 1106 performances (ie. the computation time is smaller than the 1107 motion duration). In the worst case the computation time is 1108 greater than the motion duration, but only by a small margin. 1109 As shown in Figure 20, the inverse kinematics method is 1110 currently the bottleneck of our framework and takes more than 1111 60% of the total computation time. 1112

VII. CONCLUSION

1113

In this paper we introduce a continuous, accurate and effi-1114 cient formulation of the centroidal dynamics of a legged robot, 1115 named CROC. Our method guarantees that it can compute 1116 valid centroidal trajectories that do not require discretization, 1117 1118 nor use approximation or relaxation of the dynamic constraints. This formulation is convex yet conservative, but not 1119 limited to quasi-static motions. To our knowledge, this is the 1120 first method to combine all these properties. 1121

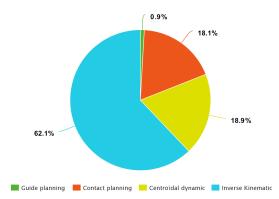

Fig. 20: Division of the computation time among the different methods of the motion planning framework.

Thanks to the computational efficiency of our method, 1122 requiring only a few milliseconds to solve the centroidal 1123 dynamic problem with three contact phases, we can use this 1124 method as a feasibility criterion during contact planning. The 1125 interest of this feasibility criterion has been demonstrated both 1126 qualitatively and empirically. Our results show that all the 1127 contact plans produced with CROC as a feasibility criterion 1128 lead to feasible centroidal dynamics problems. We also show 1129 that without using this feasibility criterion, the contact planner 1130 finds unfeasible contact sequences with a high probability on 1131 complex scenarios. 1132

Moreover, the centroidal trajectory produced by CROC can be used to provide a relevant initial guess to a non linear solver, resulting in the improvement on the convergence rate and computation time of the non linear solver by comparison to the naive initial guess previously used.

Thanks to the continuous formulation proposed in this pa-1138 per, we have the guarantee that the whole centroidal trajectory 1139 is valid, by opposition to the discretized methods of the state 1140 of the art that only guarantee that the discretized points of the 1141 trajectory are valid. We showed that the discretization may 1142 lead to a non negligible amount of invalid solutions where the 1143 trajectory is invalid between two valid discretization points, 1144 which emphasizes the interest of a continuous formulation. 1145 We believe that this continuous formulation of the constraints 1146 on the centroidal trajectory may be useful for all state-of-the-1147 art methods, convex or non-linear. We leave the study of the 1148 feasibility and the interest of this application to a future work. 1149

Finally, the feasibility criterion proposed in this paper 1150 permits us to complete our locomotion planning framework 1151 [41]. In this paper we showed that our framework is able 1152 to produce indifferently simple walking motions and multi-1153 contact motions (ie. with non coplanar contacts and acyclic 1154 behaviors). These motions were validated in simulation or 1155 on the robot HRP-2. We also showed empirically that our 1156 framework presents a success rate close to 100% and present 1157 interactive computation times (the time required to compute 1158 a motion is smaller than the duration of this motion) in the 1159 studied scenarios, except for the most complex scenario where 1160 the computation time is approximately 20% greater than the 1161 duration of the motion, but still remain in the same order 1162 of magnitude. We believe that with an optimization of the 1163

implementation, interactive performances could be achieved 1164 even in the worst cases. 1165

For future work we would like to try more complex motions 1166 on the real robotic platform, but we are currently limited by 1167 the capabilities of our low level controller. 1168

A. Handling whole-body approximations and uncertainties 1169

The remaining source of approximation is shared with all 1170 centroidal-based methods, and comes from the whole-body 1171 constraints (joint limits, angular momentum and torques), 1172 which are only approximated or ignored in the current for-1173 mulation. One solution could be to alternate centroidal opti-1174 mization with whole-body optimization as other approaches 1175 do [19], however for the transition feasibility problem, this 1176 approach would result in an increased computational burden 1177 that is not compatible with the combinatorial aspect of the 1178 search. One way to improve the quality of this approximation 1179 is to integrate torque constraints [42], [43]. Expressing such 1180 constraints at the CoM level is considered for future work. 1181

B. Application to 0 and 1 step capturability 1182

The N-Step capturability problem consists in determining 1183 the ability of a robot (in a given state) to come to a stop 1184 (ie. null velocity and acceleration) without falling by taking at 1185 most N steps. It is used to detect and prevent fall. 1186

We can easily change the constraints on c(t) defined in 1187 subsection III-A to remove the constraint on c_q and constrain 1188 $(\dot{\mathbf{c}}_q = \mathbf{0}, \ddot{\mathbf{c}}_q = \mathbf{0})$. With this set of constraints, the feasibility 1189 of FP (13) determines the 0-Step capturability. Similarly, FP 1190 (22) determines the 1-Step capturability. 1191

For future work we would like to empirically determine the 1192 accuracy of our method with respect to this problem, using a 1193 framework similar to [14]. 1194
