

Dehydrogenation vs. deprotonation of disaccharide molecules in vacuum, a thorough theoretical investigation (Supplementary Information)

Bohdan Andriyevsky, Nathalie Tarrat, Juan Cortés, and Johann Christian Schön

In the present paper, the following unified notations ${}^yX_{z';m';k'}^{z,m;k}$ of different calculated energies are used. Here, X is the calculated energy, y is the molecule of interest involved in the calculations (sucrose s , or trehalose t). The superscript $(z; m; k)$ refers to the system, for which a calculation is done, and the subscript $(z'; m'; k')$ refers to the system, from which the to-be-calculated system is extracted. Here, z is the system, which is being computed, and z' is the system, from which the to-be-computed system has been constructed. It can be: n , nominal molecule, H_i , dehydrogenated molecule with hydrogen atom H_i removed, or P_i , deprotonated molecule with proton i removed. The indices m and m' indicate the environment in which the system of interest is located: in the present study $m = m' = v$, that means vacuum. The indices k and k' indicate the kind of calculations: r , relaxed, or nr , not relaxed.

Similar notations are used for three characteristic energies corresponding to the changes of energies between different states of the molecules studied.

${}^yE_{br}^{Hi;v}$ is the break-up energy (no relaxation) of the nominal sucrose/trehalose(y) molecule into the dehydrogenated sucrose/trehalose + H-atom in vacuum, where ${}^yE_{n;v;r}^{Hi;v;nr}$ is the total energy of the non-relaxed dehydrogenated molecule, ${}^hE^v$ is the energy of the hydrogen atom and ${}^yE_{n;v;r}^{n;v;r}$ is the total energy of the relaxed nominal molecule:

$${}^yE_{br}^{Hi;v} = {}^yE_{n;v;r}^{Hi;v;nr} + {}^hE^v - {}^yE_{n;v;r}^{n;v;r}$$

${}^yE_{rel}^{Hi;v}$ is the relaxation energy of the relaxed dehydrogenated sucrose/trehalose(y) compared to the just broken-up dehydrogenated sucrose/trehalose in vacuum, where ${}^yE_{n;v;r}^{Hi;v;r}$ is the total energy of the relaxed dehydrogenated molecule:

$${}^yE_{rel}^{Hi;v} = {}^yE_{n;v;r}^{Hi;v;r} - {}^yE_{n;v;r}^{Hi;v;nr}$$

${}^yE_{rel}^{Pi;v}$ is the relaxation energy of the relaxed deprotonated sucrose/trehalose(y) compared to the just broken-up deprotonated sucrose/trehalose in vacuum, where ${}^yE_{n;v;r}^{Pi;v;r}$ and ${}^yE_{n;v;r}^{Pi;v;nr}$ are the total energy of the relaxed and non-relaxed deprotonated molecule, respectively:

$${}^yE_{rel}^{Pi;v} = {}^yE_{n;v;r}^{Pi;v;r} - {}^yE_{n;v;r}^{Pi;v;nr}$$

${}^yE_{bind}^{Hi;v}$ is the binding energy of the hydrogen atom:

$${}^yE_{bind}^{Hi;v} = {}^yE_{n;v;r}^{Hi;v;r} + {}^hE^v - {}^yE_{n;v;r}^{n;v;r}$$

Note that we also can write ${}^yE_{bind}^{Hi;v}$ as the sum of the break-up energy ${}^yE_{br}^{Hi;v}$ and the relaxation energy ${}^yE_{rel}^{Hi;v}$ of the dehydrogenated molecule: ${}^yE_{bind}^{Hi;v} = {}^yE_{br}^{Hi;v} + {}^yE_{rel}^{Hi;v}$.

I. Tables

I.1 Tables with characteristic energies of dehydrogenated and deprotonated conformations of sucrose, s1, s2, s3, and trehalose, t1, t2, t3, molecules

The labels of atoms in the columns 'Notation' of the Tables 3.1-1-3.1-12 correspond to the labels in Fig. 1 of the main paper. The order of hydrogen atoms in columns 'Notation' relates to their bonding with oxygen and carbon atoms in the molecules. Thus, $s1H_1^{O(C)}$ means that we are dealing with the hydrogen atom no. 1 of the nominal sucrose conformation s1, where the hydrogen atom is bonded to an oxygen atom, which has a bond to a carbon atom. If we are describing a dehydrogenated molecule, then we add a "v" (for vacancy) between the name of the conformation and the hydrogen atom that has been removed, e.g., $s1vH_1^{O(C)}$ refers to the sucrose conformation s1, where the hydrogen atom no. 1 has been removed. For the deprotonated molecule, we use P instead of H, to indicate that a proton and not a hydrogen atom has been removed, e.g., $s1vP_1^{O(C)}$ refers to the sucrose conformation s1, where the proton no. 1 has been removed. If it is obvious which conformation is presented, the conformation label can be dropped.

NOTE 1: In Tables 3.1-1-3.1-12 and 3.2-1-3.2-9, different hydrogen atoms, in sucrose and trehalose molecules, are indicated by different colours depending on the type of oxygen and carbon atoms they are connected to: $H_i^{O(C)}$ - black, $H_i^{C(CCO)}$ - dark red, $H_i^{C(COH)}$ - green, $H_i^{C(COO)}$ - blue. In these tables, the bold font is used to indicate the cases of the breaking up of the molecules induced by their deprotonation.

NOTE 2: In the Tables 3.1-1-3.1-12, the sign of the energies ${}^yE_{br}^{Hi;v}$ and ${}^yE_{rel}^{Hi;v}$ are positive and negative, respectively, according to the definition of the break-up and relaxation energies.

NOTE 3: The total energy of a H-atom in vacuum is equal to ${}^hE^v = -0.12$ eV.

SI-Table 3.1-1. Characteristic energies of the sucroses1, in eV. $s1E_{n;v;r}^{Hi;v;nr}$: energy for nonoptimized dehydrogenated sucrose s1 and one separated hydrogen atom; $s1E_{n;v;r}^{Hi;v;r}$: energy for optimized dehydrogenated sucrose s1 and one separated hydrogen atom; $s1E_{br}^{Hi;v}$: break-up energy (no relaxation) of the nominal sucrose s1 into the dehydrogenated sucrose s1 + H-atom in vacuum; $s1E_{rel}^{Hi;v}$: relaxation energy of the dehydrogenated sucrose s1 compared to the just broken-up dehydrogenated sucrose s1 in vacuum; $s1E_{bind}^{Hi;v}$: binding energy of the hydrogen atom is the sum of the break-up energy $s1E_{br}^{Hi;v}$ and the relaxation energy $s1E_{rel}^{Hi;v}$ of the dehydrogenated molecule. The energy of the optimized sucrose s1 $s1E_{n;v;r}^{Hi;v}$ = -227.059 eV was used for calculation of energy differences in columns no. 4 and no. 6.

SI-Table 3.1-11. Characteristic energies of the deprotonated trehalose t2, in eV. $t^2E_{n,v;r}^{Pi;v;nr}$: energy for nonoptimized deprotonated trehalose t2; $t^2E_{n,v;r}^{Pi;v;r}$: energy for optimized deprotonated trehalose t2; $t^2E_{br}^{Pi;m}$: break-up energy (no relaxation) of the nominal trehalose t2 molecule into the deprotonated one + proton in vacuum; $t^2E_{rel}^{Pi;v}$: relaxation energy of the deprotonated trehalose t2 compared to the just broken-up deprotonated one in vacuum; $t^2E_{bind}^{Pi;v}$: binding energy of the proton is the sum of the break-up energy $t^2E_{br}^{Pi;v}$ and the relaxation energy $t^2E_{rel}^{Pi;v}$ of the deprotonated molecule. The energy of the optimized trehalose t2 $t^2E_{n,v;r}^{Pi;v;r} = -226.88122$ eV was used for the calculation of energy differences in columns no. 4 and no. 6. Bold font is used for the cases of breaking the initial t2 molecule after deprotonation.

II. Figures and discussions

II.1 Figures of the three conformations of sucrose and trehalose

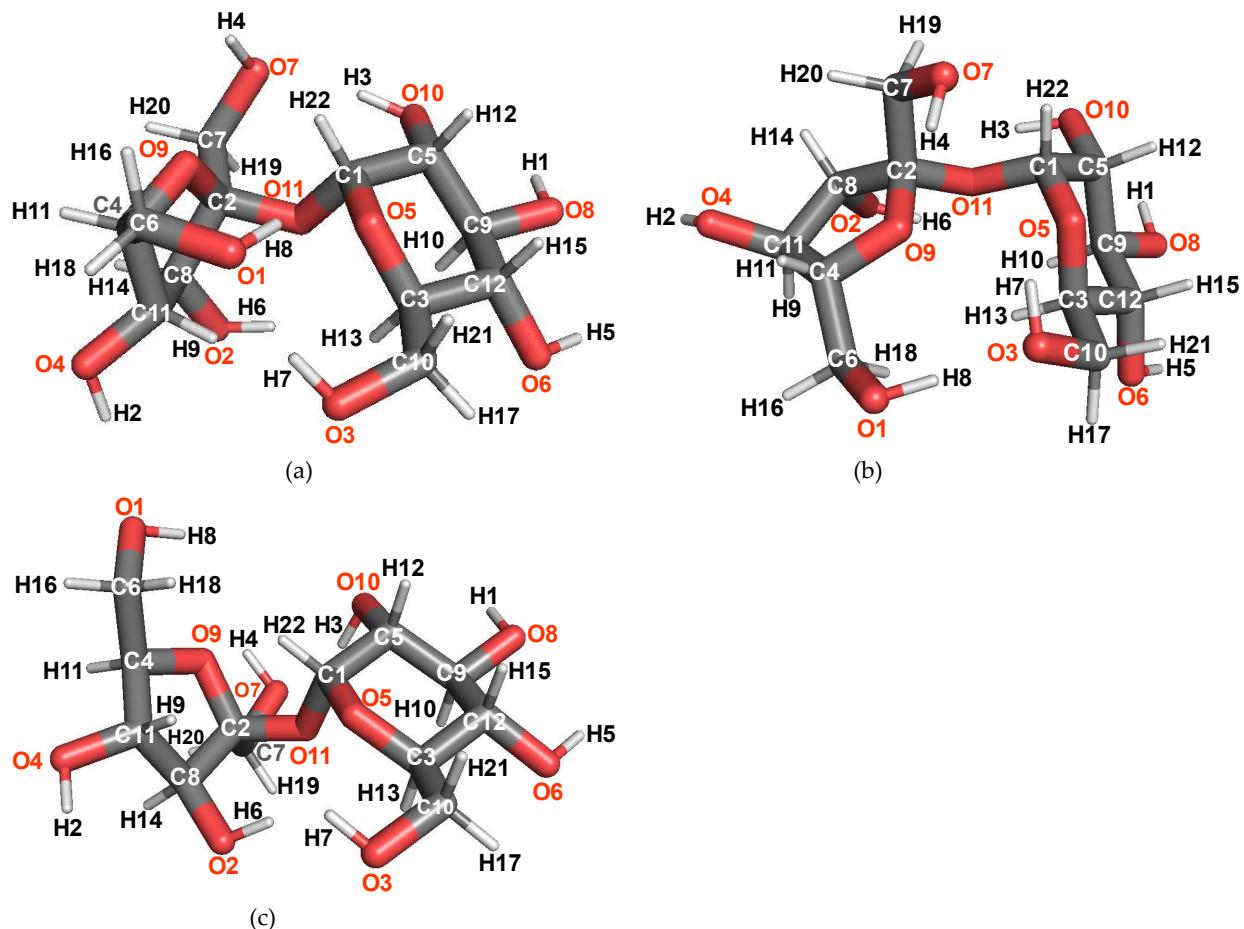

Fig. SI-1. Structures of sucrose s1 (a), sucrose s2 (b) and sucrose s3 (c). Carbon, oxygen, and hydrogen atoms are drawn in grey, red and white colors.

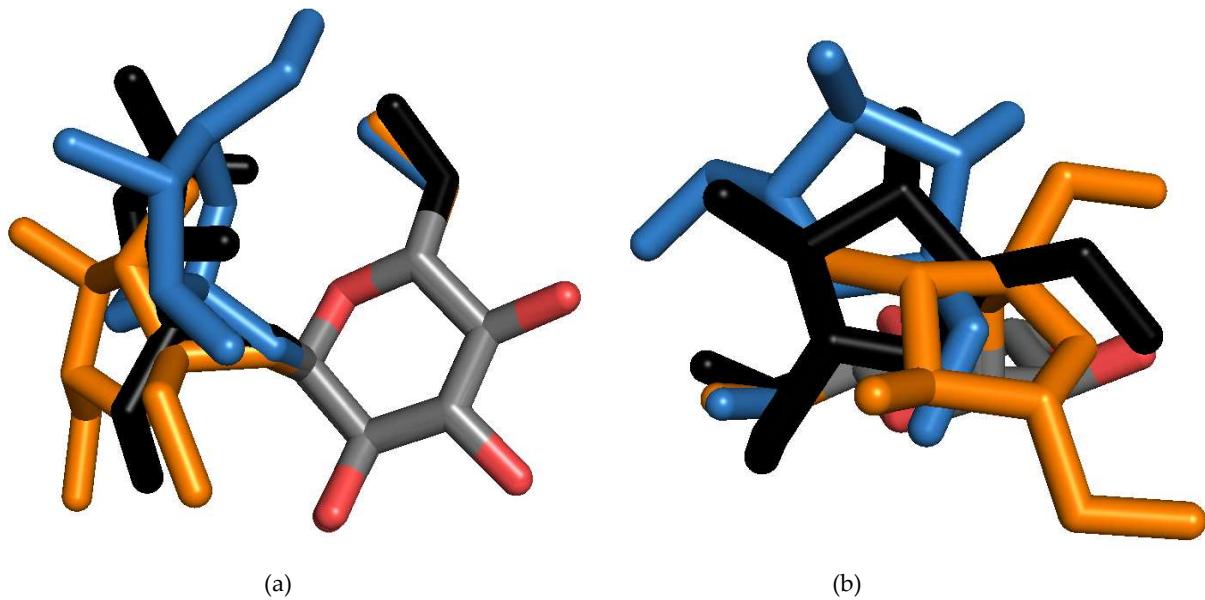

Fig. SI-2. Superimposed sucrose s1 (black), s2 (blue), and s3 (orange) structures presented from two different viewing angles, (a) and (b).

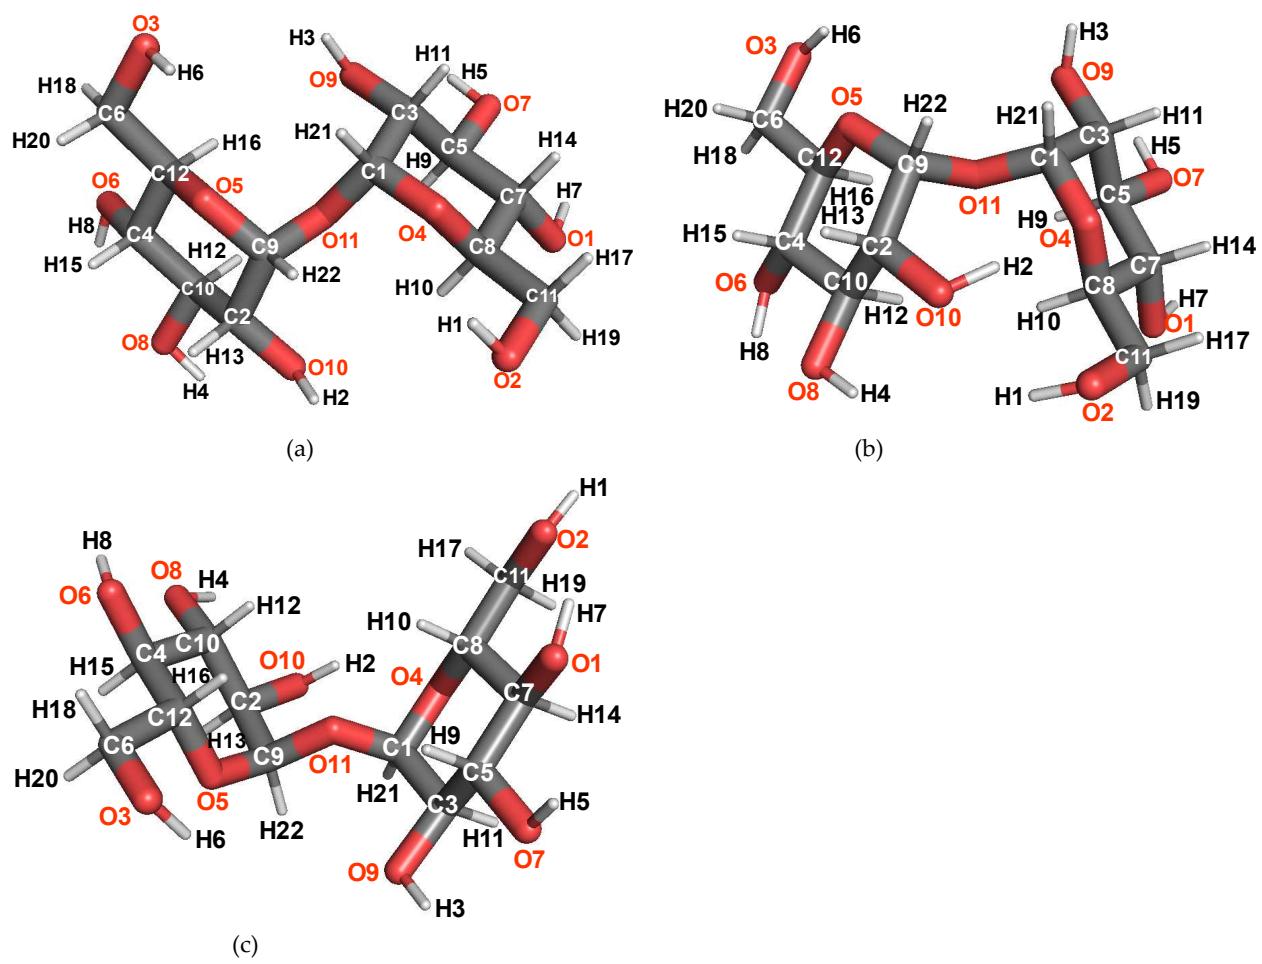

Fig. SI-3. Structures of trehalose t1 (a), trehalose t2 (b) and trehalose t3 (c). Carbon, oxygen, and hydrogen atoms are drawn in grey, red and white colors.

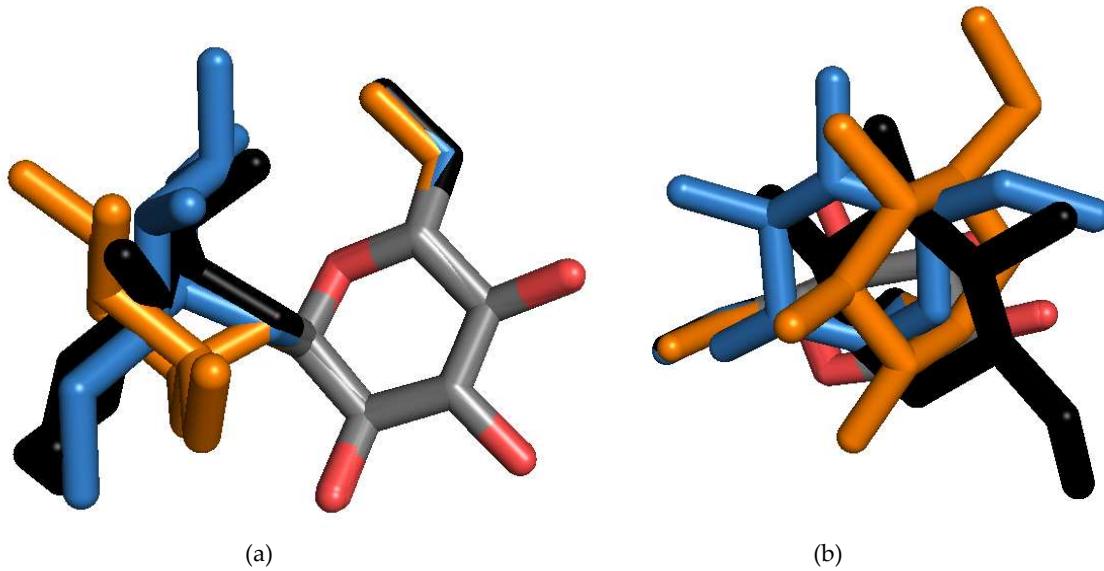

Fig. SI-4. Superimposed trehalose t1 (black), t2 (blue), and t3 (orange) structures presented from two different viewing angles, (a) and (b).

II.2 Energy calculations using the Gaussian code

In section 4.1.2 of the main text, we observe that if the proton is removed from a carbon atom, the energies of the unrelaxed deprotonated sucrose and trehalose molecules are higher than in the case when the proton has been removed from an oxygen atom. We note that we get analogous results when the Gaussian code is used for the calculations (Fig. SI-5).

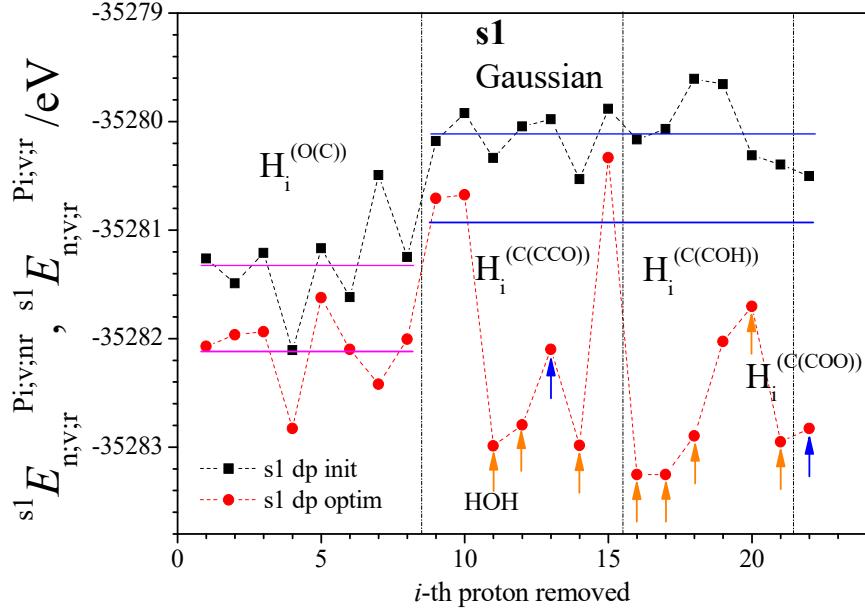

Fig. SI-5. Energies of the initial $s1 E_{n,v,r}^{P_i,v;nr}$ (black squares) and optimized states $s1 E_{n,v,r}^{P_i,v;r}$ (red circles) for deprotonated sucrose s1 as function of the i -th proton removed obtained using the Gaussian code. Horizontal lines indicate the averaged energies corresponding to the deprotonation of hydrogen atoms bonded initially to oxygen (purple) and carbon (blue) ones; only stable structures are used in these averages. Orange arrows indicate those hydrogen atoms, deprotonation of which leads to the structural destabilization and subsequent dividing of the molecule into two pieces or destruction of a 5- or 6-membered ring. Green arrows indicate those hydrogen atoms, deprotonation of which leads to the transfers to the indicated hydrogen vacancy of the nearest hydrogen atom bonded to an oxygen atom.

II.3 Electronic charges and bond analysis

In the Figs. SI-6 and SI-7 below, the NAC and BO of all hydrogen atoms for the disaccharides studied are shown, that deliver additional information to that presented in the sub-chapter 4.1.3 of the main paper. The numerical data corresponding to Figs. SI-6 and SI-7 are presented also in the form of Tables SI-3.2.1- SI-3.2.9.

It is known that the degree of ionicity (DI) of the bond between atoms A and B ($\text{DI}_{\text{A-B}}$) may be calculated using the empirical relation,

$$\text{DI}_{\text{A-B}} = \{1 - \exp[-0.25(\chi_{\text{A}} - \chi_{\text{B}})^2]\},$$

where χ_{A} and χ_{B} are the electronegativities of atoms A and B, respectively, which are available for all elements of the periodic table [1]. Thus, the calculated values of the DI using the above formula for H-O and H-C bonds are equal to $\text{DI}_{\text{H-O}} = 0.39$ and $\text{DI}_{\text{H-C}} = 0.04$. This implies that the H-O bond exhibits ionic-covalent character, whereas the H-C one is predominantly of covalent character.

A remarkable observation is the closeness of the absolute numerical values of the NACs of the hydrogen atoms in the disaccharides and the corresponding values of the DI. Therefore, one may expect that the absolute value $|(\bar{q}_{\text{A-B}^{(\text{ion})}} - q_{\text{A}^{(\text{val})}})/q_{\text{A}^{(\text{val})}}|$ is close to the $\text{DI}_{\text{A-B}}$, mentioned above. Here, $q_{\text{A-B}^{(\text{ion})}} - q_{\text{A}^{(\text{val})}}$ is the NAC of atom A, $q_{\text{A}^{(\text{ion})}}$ is the valence electron charge of the ion A in the atomic bond A - B, and $q_{\text{A}^{(\text{val})}}$ is the valence electron charge of the neutral atom A, respectively. This seems to be reasonable because the larger the absolute value of $q_{\text{A-B}^{(\text{ion})}} - q_{\text{A}^{(\text{val})}}$ is due to the electron transfer between atoms A and B, the larger is the $\text{DI}_{\text{A-B}}$.

A clear difference between the NACs of the hydrogen atoms in the sucrose and trehalose molecules is observed when comparing the H-O and H-C bonds, which correlates with the different degrees of ionicity (SI-Table 3.2-1, and Fig. SI-6): the NACs are much larger when hydrogen belongs to the hydroxyl groups than when it is bonded to carbon atoms. This indicates a relatively high ionicity of the H-O bonds and a low ionicity of the H-C bonds in these molecules.

We observe a slightly larger value of the averaged NAC for hydrogen in H-O bonds for trehalose than for sucrose (Fig. SI-6), and the opposite holds true for the NACs of the hydrogen atoms in H-C bonds of trehalose and sucrose (Fig. SI-6). However, we note that the charge differences are at the limit of accuracy of the computational methods, and thus should not be over-interpreted.

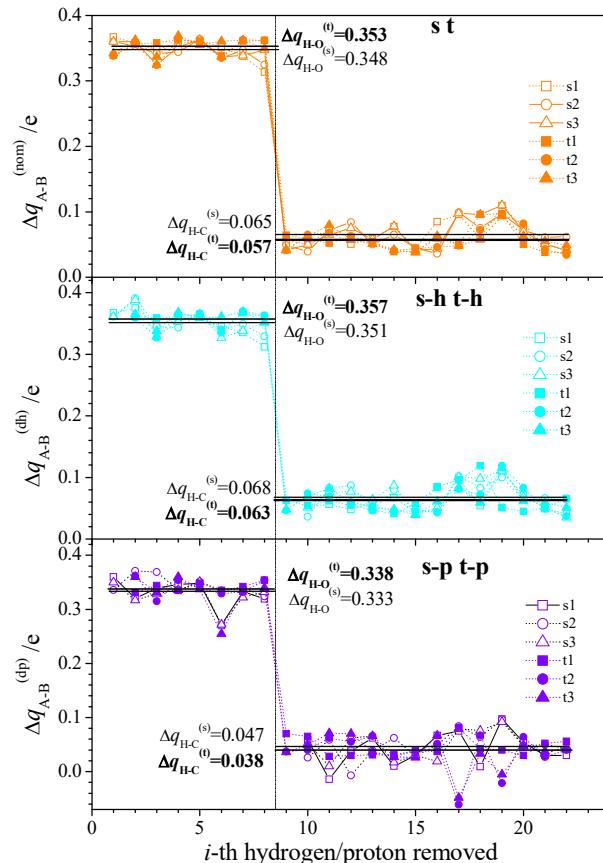

Fig. SI-6. NAC ($\Delta q_{\text{A-B}} = q_{\text{A-B}^{(\text{ion})}} - q_{\text{A}^{(\text{val})}}$) of hydrogen atoms for the nominal (nom), dehydrogenated (dh) and deprotonated (dp) sucrose and trehalose molecules. The horizontal lines indicate the averaged NACs over three disaccharide conformations (s1, s2, s3 or t1, t2, t3) and hydrogen atoms locations (H-O or H-C). Note that the average values for the trehalose and sucrose conformations are very close.

In all three forms of the disaccharides studied, nominal, dehydrogenated and deprotonated, the BOs of hydrogen atoms in the H-C bonds are larger than those in the H-O bonds (Fig. SI-7). This feature is the converse to what we saw for the corresponding NACs (Fig. SI-6), and this agrees with the intuitive interpretation that the BO mainly reflects the degree

of covalency of the bond. In most cases (Fig. SI-7), the BOs for the hydrogen atoms in sucrose are slightly larger than those for trehalose. This is in agreement with the opposite behavior of the corresponding NACs (Fig. SI-6), which depends mainly on the DI of the bond. Furthermore, we note that while the bond orders of the hydrogen atoms in the nominal and dehydrogenated molecules are quite similar (at least on average), the ones for the deprotonated molecules are considerably larger, especially for the hydrogen atoms associated with an oxygen atom. This most likely reflects the presence of the excess electron compared with the case of the dehydrogenated molecules.

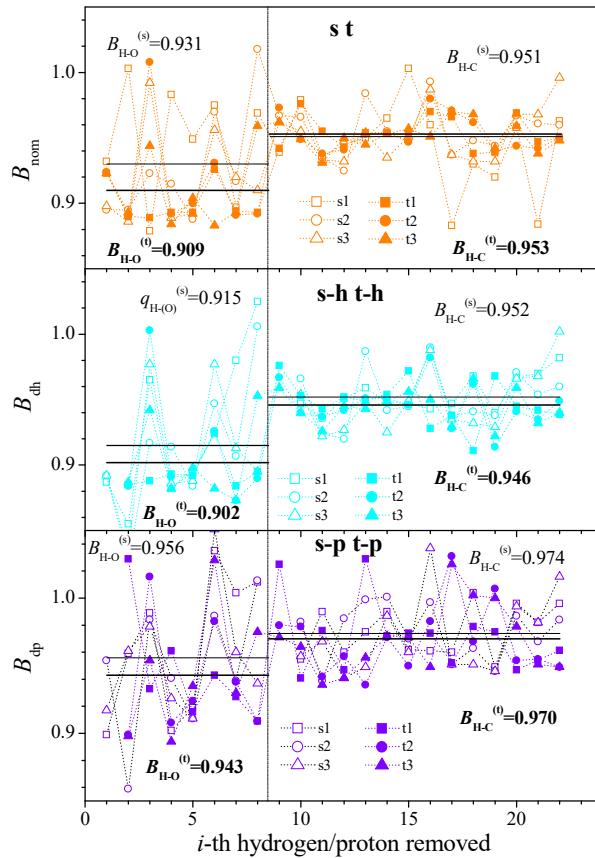

Fig. SI-7. BO (B) of hydrogen atoms for the nominal (nom), dehydrogenated (dh) and deprotonated (dp) sucrose and trehalose molecules. The horizontal lines indicate the averaged BOs over three disaccharide conformations (s1, s2, s3 or t1, t2, t3) and hydrogen atoms locations (H-O or H-C).

We also found that, for sucrose s1 and trehalose t1 molecules, the BOs of hydrogen (~0.94) and carbon (~3.91) atoms are slightly smaller (on average) than the corresponding valences of the chemical elements (1 for hydrogen and 4 for carbon), while for oxygen atoms the bond order (~2.26) is about 11% larger (on average) than the corresponding valence (2). The latter feature may be due to the participation of the lone electron pairs of oxygen in the interatomic bonding [2, 3]. In this context, we note that "bond order" is a rather subtle entity, whose definition employs both rigorous quantum mechanical considerations and chemical intuition, c.f. [4]. Note that what we call the bond order parameter (BO) in this study corresponds to the SBO (= Sum of Bond Orders) in the paper by Manz [4].

These considerations are also relevant for the case presented in Fig. SI-8, which concerns the transfer of two hydrogen atoms (H3 and H4). This rearrangement takes place when the optimized dehydrogenated neutral sucrose s1 structure (with the removed hydrogen atom of the type $\text{H}^{\text{C}(\text{COO})}$ from the position near to the carbon atom C1) becomes negatively charged by adding an electron; this corresponds to an effective deprotonation since we can formally visualize a deprotonation as the removal of a hydrogen atom (= proton + electron) followed by an addition of an electron. After adding the electron, the initial dehydrogenated structure becomes unstable and transforms to a new structure. During this transformation, the two hydrogen atoms (H3 and H4), which are neighbours to the initial proton vacancy $\text{dpH}^{\text{C}(\text{COO})}$ at the carbon atom, simultaneously change their positions in such a concerted way that the vacancy $\text{dpH}^{\text{C}(\text{COO})}$ moves to the nearest oxygen atom. This process corresponds to the quasi-monotonous decrease of energy of sucrose s1 found using the NEB method (Fig. SI-9).

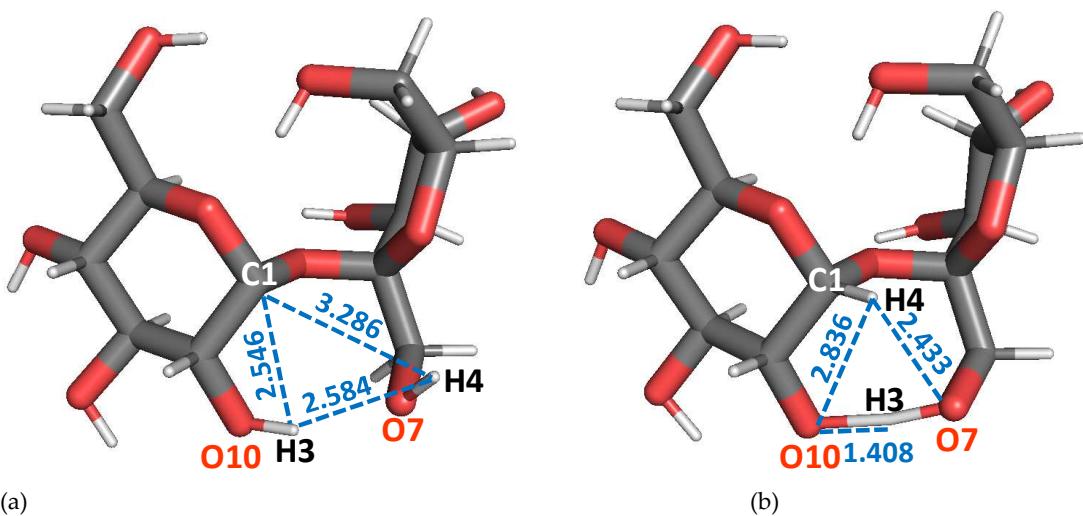

Fig. SI-8. Fragments of the atomic structure of the dehydrogenated (a) and deprotonated (b) sucrose s1. Here, the hydrogen atom $H^{C1(C5O5O11)}$ (H22) had been removed from the carbon atom C1 upon dehydrogenation/deprotonation (this is the vacancy dpH22). Interatomic distances are indicated in Angstrom.

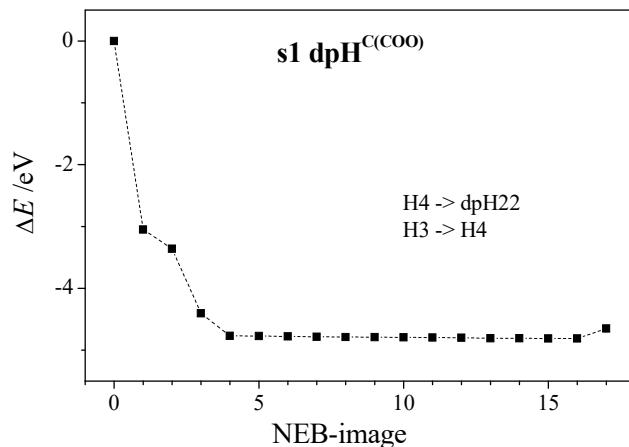

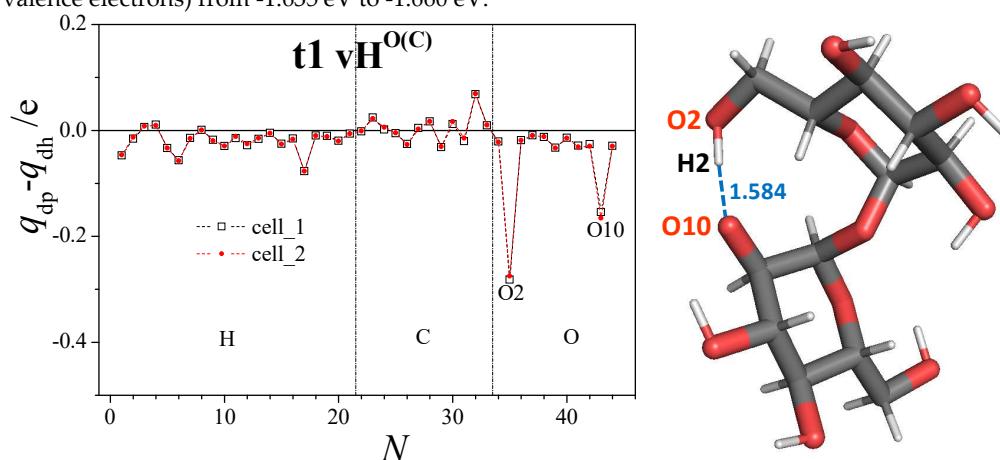

Fig. SI-9. Energy variation ΔE of the deprotonated $dpH^{C(COO)}$ sucrose s1 during the concerted transfer of H3 and H4 (see Fig. SI-8).

In contrast to the sucrose s1 molecule in Fig. 8 in the main text, Fig. SI-10 presents the dehydrogenated/deprotonated trehalose t1, where the initial position of the removed hydrogen atom/proton was near the oxygen O2 atom, but where the deprotonation leads to structural changes. During the deprotonation and subsequent structure relaxation, the hydrogen atom H2 was transferred from its initial location at the oxygen atom O10 to the oxygen atom O2, and, conversely, the proton vacancy moved from O2 to O10. Deprotonation leads to the increase of the absolute values of negative charge of both neighbouring oxygen ions O2 and O10 (Fig. SI-10a). Here, the hydrogen H2 transfer (and corresponding structure optimization) is accompanied by the decrease of the specific energy (energy per number of valence electrons) from -1.635 eV to -1.660 eV.

(a) (b)

Fig. SI-10. (a) Change of charges, $q_{dp} - q_{dh}$, for hydrogen, carbon and oxygen atoms of the deprotonated trehalose t1 compared to the dehydrogenated one in cell_1 ($V_1 = 10.7 \text{ nm}^3$) and cell_2 ($V_2 = 125 \text{ nm}^3$). (b) View of the atomic structure of deprotonated trehalose t1. Before the initial deprotonation at the oxygen atom O2, the hydrogen atom H2 of the type $\text{H}^{\text{O}(\text{C})}$ had been bonded to the oxygen atom O10. The interatomic distance is indicated in Angstrom.

Overall, we do not find large differences of NACs between sucrose and trehalose molecules: the positive NACs of hydrogen atoms are 2% larger in sucrose than in trehalose, the average positive NACs of carbon are 6% smaller in sucrose than in trehalose, and the average negative NACs of oxygen in sucrose and trehalose differ by less than 0.3%. However, we see that the negative NAC of the bridge oxygen atom is larger for sucrose s1 than for trehalose t1 (c.f. SI-Table 3.2-10). Furthermore, in sucrose s1, the average positive NAC of the five-member ring is 53% larger than the one of the six-member ring. The smaller negative charge of the five-membered ring of sucrose may cause a decrease in the structural stability of these rings when, e.g., the deprotonation occurs in this ring. It is also well-known that ring tension makes small rings more unstable than large ones. Such a structural instability with broken five-membered rings is actually observed during the deprotonation of the sucrose molecule. In contrast, in trehalose t1, the positive NACs of the two six-membered rings are almost equal. Thus, the larger asymmetry of sucrose in comparison to trehalose leads also to the larger difference in NACs of the five- and six-member rings.

For mid-sized molecules, like sucrose and trehalose, the interatomic interactions beyond nearest-neighbour atoms and their changes upon dehydrogenation and deprotonation can substantially influence the total energy of a molecule. Compared to the overall vdW interaction, the strength of the hydrogen bonds in the disaccharide molecules may be relatively large. Using the DDEC6 method we have calculated for different configurations of the disaccharides the sum of overlap populations of hydrogen and oxygen atoms. Here, we have excluded the overlap populations corresponding to the short distances $d_{\text{H-O}} \approx 1.0 \text{ \AA}$ associated with ionic/covalent H-O bonds, since they do not relate to the hydrogen bonding in the molecule. Some weak correlation between the sum of H-O overlap populations $\Pi_{\text{H-O}}$ and the total energy E can be seen in Fig. SI-11 for the dehydrogenated and deprotonated molecules. This may indicate the influence of the hydrogen bonding H-O on the overall bonding in the molecule: the larger the sum of the H-O overlap population $\Pi_{\text{H-O}}$, the larger the energy of the H-O interaction $E_{\text{H-O}}$, and thus the larger the absolute value of total energy E of the whole molecule. Following this line of argument and taking into account Fig. SI-11, one notes a trend in this influence from the neutral (nominal and dehydrogenated) to the deprotonated disaccharide.

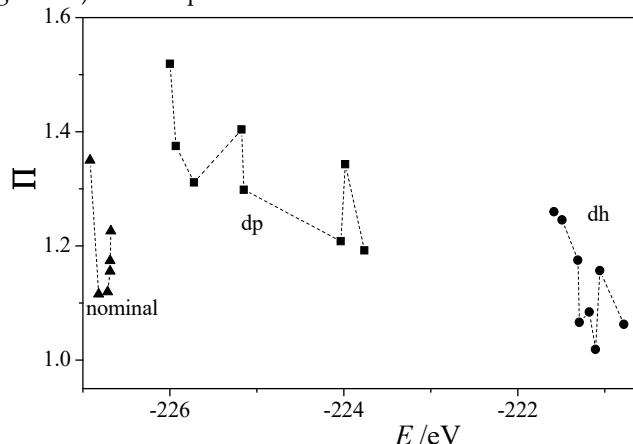

Fig. SI-11. Sum of overlap populations Π of the atom pairs H-O (excluding the eight shortest H-O distances of approximately 1 Å, which do not contribute to hydrogen-bridge bonds) as a function of total energy E for six nominal disaccharide modifications s1, s2, s3, t1, t2, t3 (left part of the graph), eight dehydrogenated modifications (four sucrose-based plus four trehalose-based, in right part of the graph) and eight deprotonated modifications (four sucrose-based plus four trehalose-based, in middle part of the graph).

II.4 NEB calculations

As mentioned earlier, the structure where the hydrogen atom is removed from an oxygen atom has a higher specific energy than the one where the H-atom is removed from a carbon atom (Figs. 5, 6 in the main text). This means that the total energy of the relaxed dehydrogenated sucrose or trehalose molecule is minimal when the hydrogen atom is removed from one of the carbon atoms and thus all eight O-H bonds are present in the dehydrogenated molecule (this is equivalent to the fact that O-H bonds are stronger than C-H ones and the former ones deliver a larger contribution to the total energy of the molecule). As a consequence, in all those cases where the hydrogen transfer in dehydrogenated molecules occurs between an oxygen atom and a carbon atom that are direct neighbours, the structure with the transferring hydrogen atom located at the carbon atom has a higher energy than the one with the transferring hydrogen atom located at the oxygen atom (see Figs. SI-12b, c, d and Fig. SI-13a). This is true not only in relation to the total energy E (Figs. 11 and 12 in the main text) but also in relation to the specific energy E_{1e} . This specific energy allows us to compare the energies E_{1e} of the dehydrogenated and deprotonated disaccharides, which have different numbers of bonding electrons (135 and 136, respectively). One can observe a clear difference in the specific energy E_{1e} between dehydrogenated and deprotonated disaccharide molecules (Figs. SI-12b, c, d and Fig. SI-13a). The addition of one electron to the dehydrogenated disaccharide (corresponding to a deprotonation), with the hydrogen vacancy at an oxygen atom, decreases the specific energy substantially (see Figs. SI-12b, c, d, and also Fig. SI-13a for NEB images of a hydrogen atom located at carbon $H^{C(CCO)}$, for the cases of H^O to $H^{C(CCO)}$ transfers). This is probably caused by the additional electron charge localization (due to deprotonation) at the proton vacancy near the oxygen atom (this corresponds to the NEB image of a hydrogen atom localized at a carbon atom of type $H^{C(CCO)}$). The latter assumption is supported by the charges of the atoms in the deprotonated sucrose s1 obtained using the DDEC6 method (Fig. SI-6).

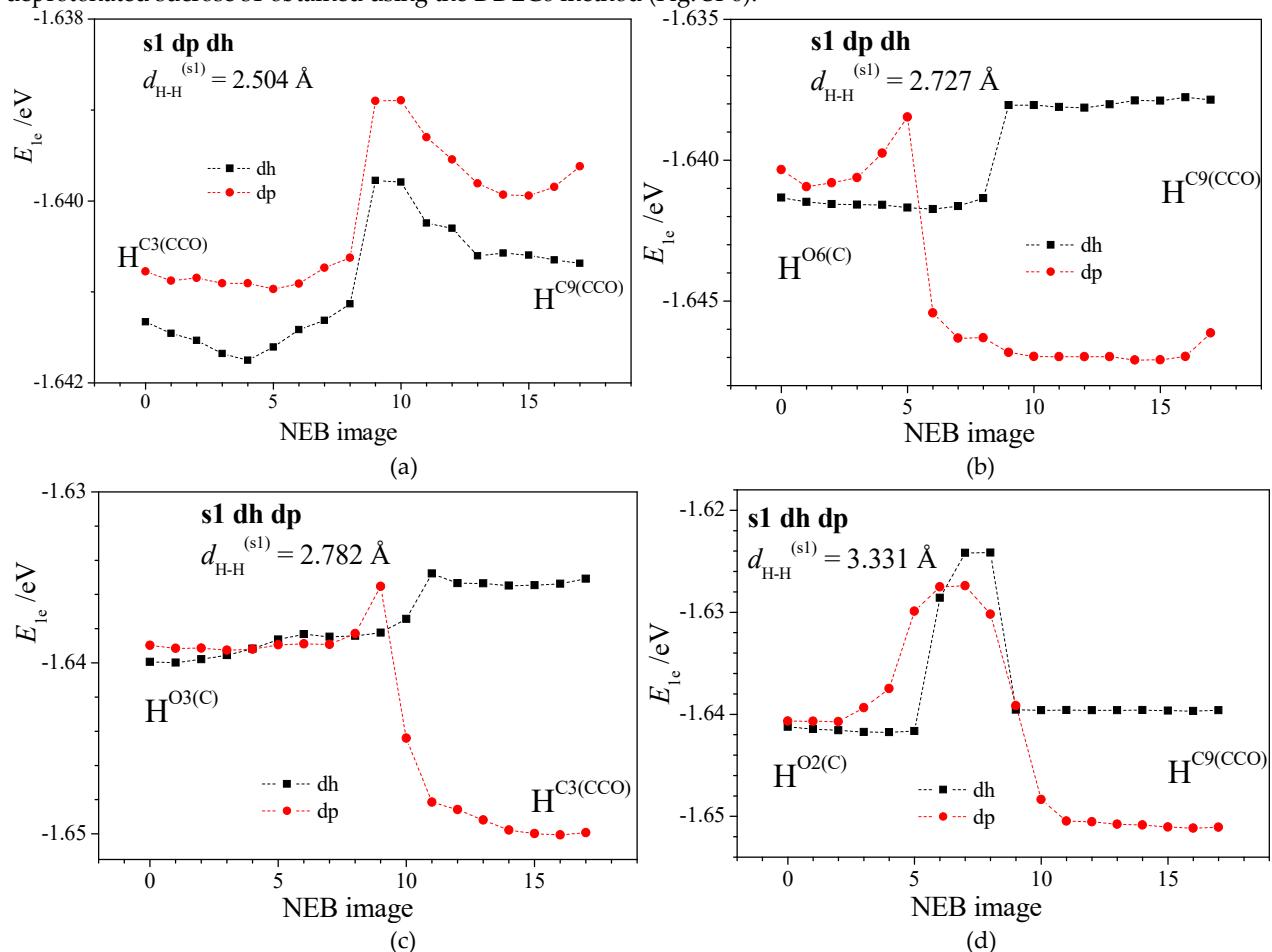

Fig. SI-12. Specific energy changes E_{1e} vs. NEB hydrogen atom images in dehydrogenated (dh) and deprotonated (dp) sucrose s1 for hydrogen transfers between different optimized positions: (a) $\text{H}^{\text{C}3(\text{CCO})}$ - $\text{H}^{\text{C}9(\text{CCO})}$, (b) $\text{H}^{\text{O}6(\text{C})}$ - $\text{H}^{\text{C}9(\text{CCO})}$, (c) $\text{H}^{\text{O}3(\text{C})}$ - $\text{H}^{\text{C}3(\text{CCO})}$, (d) $\text{H}^{\text{O}2(\text{C})}$ - $\text{H}^{\text{C}9(\text{CCO})}$. $d_{\text{H-H}}$ is the interatomic distance H-H between hydrogen atoms in the relaxed nominal molecule, which are shifted in the NEB calculation.

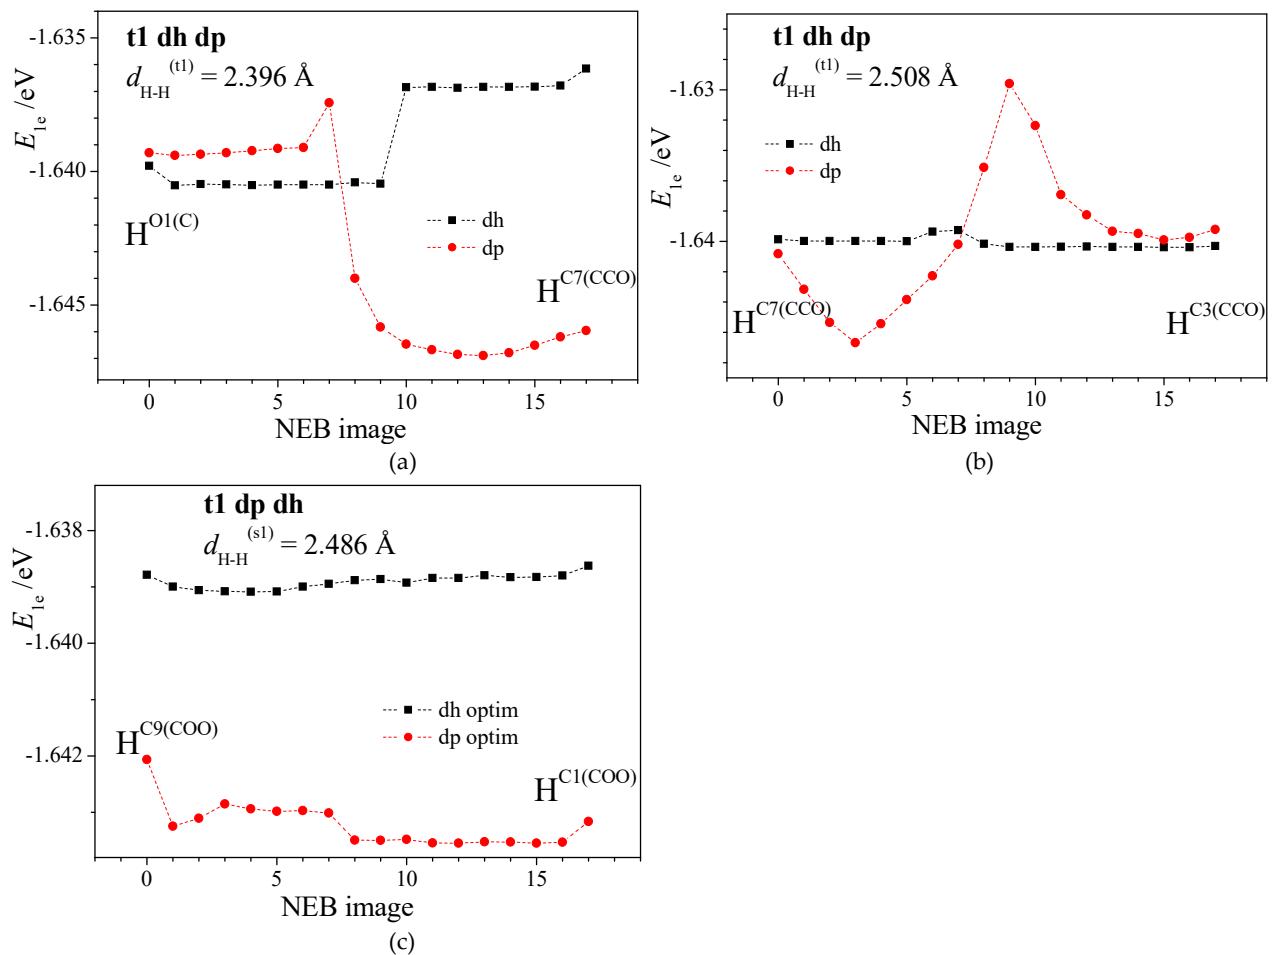

Fig. SI-13. Specific energy changes E_{1e} vs. NEB hydrogen atom images (a, b, c) in dehydrogenated (dh) and deprotonated (dp) trehalose t1 for hydrogen transfers between different optimized positions: (a) $\text{H}^{\text{O}1(\text{C})} - \text{H}^{\text{C}7(\text{CCO})}$, (b) $\text{H}^{\text{C}7(\text{CCO})} - \text{H}^{\text{C}3(\text{CCO})}$, (c) $\text{H}^{\text{C}9(\text{COO})} - \text{H}^{\text{C}1(\text{COO})}$. $d_{\text{H-H}}$ is the interatomic distance H-H between hydrogen atoms in the relaxed nominal molecule, which are shifted in the NEB calculation.

II.5 Radial distribution function

In figure SI-14, we show the total RDF for the three conformations of the nominal sucrose and trehalose molecules up to moderately short distances of 3 Å. We note that the very short atom-atom distances (≤ 1.6 Å), which correspond to the covalent bonds between the atoms, are essentially the same for all conformation and molecules. Even at the larger distances, the radial distributions exhibit peaks and valleys at the same positions, but with slight shifts and variations in the amplitude.

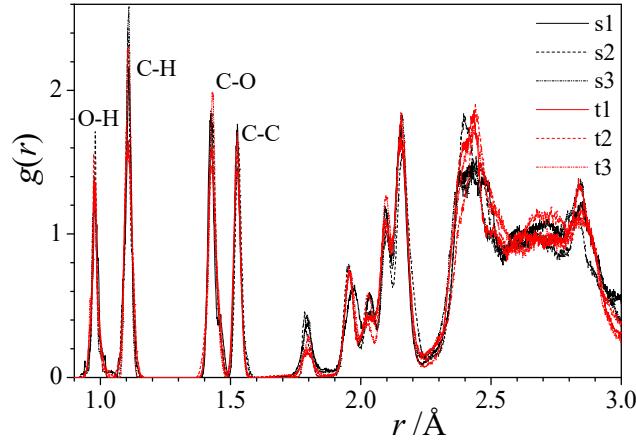

Fig. SI-14. Total RDF $g(r)$ for the nominal sucrose s_1 , s_2 , s_3 and trehalose t_1 , t_2 , t_3 modifications in the range of 0.9 – 3 Å. Note that the integrals $\int g(r)dr$ over the range of 0 - 3 Å has the same value for each of the six molecules [5]. The four first peaks correspond to the shortest O-H, C-H, C-O, and C-C bonds, that can be obtained from the partial (pair-wise) RDF.

II.6 Some comments on the concept of relaxation energies

After the removal of an atom or charged species from a molecular system, the remaining system is in a very high energy state, both regarding its possibly distorted structure (compared to a relaxed minimum energy structure) and with respect to its electronic state. Consequently, the system will tend to relax to a (local) minimum energy state by various mechanisms.

The classical ways of energy loss for organic systems are thermal, i.e., non-radiative. This can occur via vibrational relaxation, i.e., via what is considered in chemistry as internal conversions [6] or intersystem crossings which are radiation-less transitions from a high to a low molecular electronic state, where the energy is being transformed to heat. Note that the difference between these two mechanisms is the retention (internal conversion) or the non-retention (intersystem crossing) of the spin state.

One can also mention external conversion, in which an electronically excited molecular state relaxes to a lower one or even reaches the electronic ground state by collisions with other species of the medium. This is, for example, the mechanism involved in solvent relaxation. Another important way for the molecular system to reduce its energy is via the fragmentation of the molecule, which we have observed in a number of cases in our present study.

Of course, these non-radiative processes compete, in principle, with radiative de-excitations where a photon of the right wave length is emitted. But even in this case, the radiation based relaxation process would be accompanied by a structural adjustment of the molecule involving vibrational relaxations.

In order to avoid confusion, we note that, in physics, the term internal conversion is not only used for the analysis of chemical systems but is often also applied to the non-radiative relaxations of radioactive nuclei or of nuclear reaction products, where the energies involved are typically several orders of magnitude larger than the ones encountered in chemical systems. Here, the excitation energy of an atomic nucleus is transferred to an electron which is ejected from the atom (two other important nuclear energy relaxation pathways are the emission of gamma rays and the creation of particle-antiparticle pairs). Finally, we note the Auger effect, which describes the relaxation of a high energy state of a molecule or atom, where an energetically deep-lying electron had been ejected from an atom/molecule or moved into a high excited state, through a two-electron process where one of the valence electrons moved into the empty state and the energy associated with this transition is not released via an X-ray photon but is used to kick out another electron from the valence shell.

In the present study, we focus on energy relaxation via structural reorganization of a molecule, without or with fragmentation.
