ABSTRACT. We propose to approximate a (possibly discontinuous) multivariate function \( f(x) \) on a compact set by the partial minimizer \( \arg \min_y p(x,y) \) of an appropriate polynomial \( p \) whose construction can be cast in a univariate sum of squares (SOS) framework, resulting in a highly structured convex semidefinite program. In a number of non-trivial cases (e.g. when \( f \) is a piecewise polynomial) we prove that the approximation is exact with a low-degree polynomial \( p \). Our approach has three distinguishing features: (i) It is mesh-free and does not require the knowledge of the discontinuity locations. (ii) It is model-free in the sense that we only assume that the function to be approximated is available through samples (point evaluations). (iii) The size of the semidefinite program is independent of the ambient dimension and depends linearly on the number of samples. We also analyze the sample complexity of the approach, proving a generalization error bound in a probabilistic setting. This allows for a comparison with machine learning approaches.

1. Introduction

Approximation of discontinuous functions in multiple dimensions is a notoriously difficult problem and a scientific challenge. A common strategy (e.g. described in [26]) which works well in the univariate setting (and is implemented for example in the chebfun package [10]) consists of the following steps: 1) detect the discontinuity locations and split the domain into a disjoint union of regions where the function is continuous, and 2) construct approximations of the continuous pieces on each region. However, in the multivariate case this strategy is very challenging to implement since the discontinuity set may have a positive dimension (see, e.g, [15] where an algorithm for detecting discontinuities in two dimensions is proposed). Numerical difficulties faced with approximating multivariate functions are illustrated in the example sections of the paper.

A typical and important application is concerned with classification in data analysis and supervised learning, where powerful deep learning methods have obtained impressive results and success stories. However, such powerful methods still have some limitations (even for learning continuous functions, let alone discontinuous functions). Indeed for instance and quoting [3], “Despite many results that establish the existence of Neural Nets (NNs) with excellent approximation properties, algorithms that can compute these NNs only exist in specific cases.” That is, no training algorithm can obtain them in the general case. For an interesting discussion about such limits (instability, accuracy, etc.) the interested reader is referred to [2, 3] and references therein. For learning discontinuous functions by neural networks, [14] proposes a tailored architecture; however this approach requires the knowledge of the discontinuities locations and is limited to univariate problems.

In this paper we provide an alternative approximation technique aimed at dealing with such discontinuities and the Gibbs phenomenon, which are large oscillations of the approximation near the discontinuity points, see e.g. [24, Chapter 9]. In particular, we show that our class of approximants can model exactly multivariate piecewise polynomial functions and can approximate with arbitrary accuracy other discontinuous functions.

Prior work. The idea behind our new approximant is a non-trivial extension of our previous work [18] that has provided an approximant which is the argument of the partial minimum (argmin), of a sum of squares (SOS) of polynomials, in fact the reciprocal of the Christoffel function of a measure, ideally supported on the graph of the function to recover. As explained in [18], this recovery procedure can be seen as a non-standard application of the Christoffel-Darboux kernel. Importantly, being in a class of functions much larger than polynomials, such an approximant is able to approximate some discontinuous functions much better than polynomials can.

Remarkably, in non-trivial examples, recovery is possible without oscillations and Gibbs phenomenon usually encountered in several more standard approaches. In this respect the reader is referred to the detailed discussion in [25] on kernel variants (e.g. Féjer or Jackson kernels) to attenuate the Gibbs phenomenon encountered with polynomial approximations.

This paper can be considered both as a follow-up and a non trivial extension of [18].

Contribution. Inspired by [18] we introduce a new class of approximants for a possibly discontinuous function \( f \) from \( X \subset \mathbb{R}^n \) to \( Y \subset \mathbb{R} \). We propose to approximate \( f \) by the polynomial argmin

\[
(1.1) \quad x \mapsto \hat{f}(x) := \min\{ \arg\min_{y \in Y} p(x, y) \}, \quad x \in X,
\]

where \( Y \supset f(X) \) and \( p \in \mathbb{R}[x, y] \) is a polynomial in \((x, y)\).

The main features of our approach can be summarized as follows.

- The approach is mesh-free and does not require the knowledge of the discontinuities locations.
- It is not limited to univariate functions or tensor products thereof.
- It is model-free, working only with the samples of the unknown function.
- The approximant is constructed using a very specific class of convex optimization (semidefinite programming) problems whose size depends (linearly) on the number of samples but not on the ambient dimension.
- It is simple to evaluate as it is the argmin of a univariate polynomial.
- We provide a generalization error analysis in a probabilistic setting.

We believe that these features make the approach a unique and promising tool with a wide variety of applications in data analysis. This is corroborated by a numerical evidence where we observe a remarkable performance on a range of examples. We also provide a solid theoretical underpinning of the method but leave some questions open, including the optimal rate of convergence of the argmin approximant.

A novelty and distinguishing feature with respect to [18] is that the polynomial \( p \) in (1.1) is not restricted to be the reciprocal of the Christoffel function associated with the measure supported on the graph of \( f \). Indeed, our set of potential candidate polynomials \( p \) is now a suitably chosen subspace of \( \mathbb{R}[x, y] \), which is much larger than the set considered in [18].

While our original motivation for introducing the polynomial argmin approximant was to recover the solution of a nonlinear partial differential equation from the knowledge of its approximate moments [17], this strategy was made rigorous and generalized to graph recovery from moments [18]. Then it was extended to cope with partial moment information [13]. Following our initial
work, this argmin strategy was called “implicit model” and used in robotics applications \cite{12} where the polynomial \( p \) in (1.1) is replaced by a continuous function computed by training, e.g. a neural network.

**Outline.** In the motivational Section 2 we show that our polynomial argmin strategy is already efficient in some non-trivial cases. For instance, it allows *exact recovery* when \( f \) is a polynomial, or an algebraic function, or a piecewise polynomial. In particular it can model exactly the indicator function of the unit disk, sharply contrasting with classical approximants.

However, exact recovery by a polynomial argmin cannot be guaranteed in general, and in Section 3 we provide a numerical scheme to obtain the polynomial \( p \) in (1.1) when knowledge on \( f \) is only though its finitely many values on a sample of points \((x(i))_{i \in I} \subset X\) (without a priori knowledge on its distribution). We reformulate our polynomial argmin strategy in the framework of sum of squares (SOS) positivity certificates so that finding \( p \) amounts to solving a semidefinite optimization problem whose size is controlled by the degree of \( p \) in \( y \) and the sample size.

Finally, in Section 4 we also provide a set of numerical experiments to evaluate the efficiency of our proposed polynomial argmin strategy on a sample of problems. We observe that it performs remarkably well to approximate challenging discontinuous functions already tested in \cite{18}, as well as non-trivial two-dimensional examples of functions whose set of discontinuities has positive dimension. We have also compared with machine learning methods based on neural networks. In all our experiments, the proposed method achieves far better accuracy with simpler representation of the approximant.

### 2. Motivating examples

The purpose of this section is to demonstrate the expressive power of the polynomial argmin. We do so by showing that for several classes of known functions, an exact (and sometimes obvious) representation is possible. Subsequently, in Section 3 we show how a polynomial argmin approximation can be found using convex optimization, provided that some finite sample of values of \( f \) is available. Importantly, all polynomials of the illustrative examples below are indeed optimal solutions of the convex program alluded to, which supports the claim that in some sense the optimization problem is well-founded as natural obvious solutions of those illustrative examples can be recovered.

#### 2.1. Polynomials.

When \( f \in \mathbb{R}[x] \) is a given polynomial, we can choose in (1.1)

\[
p(x, y) := \frac{1}{2} y^2 - f(x) y.
\]

Indeed, we observe that \( \frac{dp}{dy} = y - f(x) \) and hence \( y = f(x) \) is a stationary point. Since \( p \) is strictly convex in \( y \), it follows that \( y = f(x) \) is the global minimizer. The degree of \( p \) in \( x \) is equal to the degree of \( f \) whereas the degree in \( y \) is equal to two irrespective of \( f \).

#### 2.2. Algebraic functions.

An algebraic function \( f \) is such that \( q_k(x, f(x)) = 0 \) for some given polynomials \( q_k \in \mathbb{R}[x, y], k = 1, \ldots, m \).

If for each \( x \), \((x, f(x))\) is the unique common zero of the \( q_k \) then we can readily choose

\[
p(x, y) := \sum_{k=1}^{m} q_k(x, y)^2
\]

and observe that the degree of \( p \) in \( x \) and \( y \) is twice the maximal degree of the \( q_k \) in these variables.
Note that semi-algebraic functions\(^1\) can also be modeled like that, provided that the inequalities are incorporated in the definitions of the domain \(X\) and image sets \(Y\).

**Example 1.** The absolute value function can be expressed as

\[
|x| = \arg\min_{y \in \mathbb{R}} (x^2 - y^2)^2
\]

with \(Y := [0, 1]\), for all \(x \in X := [-1, 1]\). Note that a more complicated degree 8 polynomial \(arg\min\) model for the absolute value function was already described in \cite{18} Example 2.

### 2.3. Piecewise polynomials.

Let \(g, p_1, p_2 \in \mathbb{R}[x]\) and consider the piecewise polynomial function

\[
 f(x) := \begin{cases}
 p_1(x) & \text{if } g(x) \in (0, 1) \\
 p_2(x) & \text{if } g(x) \in (-1, 0)
\end{cases}
\]

for \(x \in X := \{x : g(x) \in (-1, 0)\} \cup \{x : g(x) \in (0, 1)\}\).

**Lemma 2.1.** There exists \(p \in \mathbb{R}[x, y]\) such that \(f(x) = \arg\min_{y \in \mathbb{R}} p(x, y)\) for all \(x \in X\), with \(Y = \mathbb{R}\).

**Proof:** With \(r \in \mathbb{R}[x]\) and \(q \in \mathbb{R}[x, y]\), let \(p(x, y) := (y - p_1(x))^2(1 - y - p_2(x))^2 + r(x)q(x, y)\) be such that \(\partial q(x, y)/\partial y = 6(y - p_1(x))(1 - y - p_2(x)).\) For instance \(q(x, y) := 2y^3 - 3(p_1(x) + p_2(x))y^2 + 6p_1(x)p_2(x)y\). Now observe that for each given \(x \in X\), \(y \mapsto p(x, y)\) is a coercive quartic univariate polynomial, and hence it has at most two local minima. Letting \(r(x) := g(x)(p_1(x) - p_2(x)),\) the gradient \(\partial p(x, y)/\partial y\) vanishes at the critical points \(p_1(x)\) resp. \(p_2(x)\) resp. \(p_3(x) := (p_1(x)(1 - 3g(x)) + p_2(x)(1 + 3g(x)))/2\). At the critical points the Hessian \(\partial^2 p(x, y)/\partial y^2\) is equal to \(2(p_1(x) - p_2(x))^2/(1 + 3g(x))\) resp. \(2(p_1(x) - p_2(x))^2/(1 - 3g(x))\) resp. \(2(p_1(x) - p_2(x))^2/(1 + 3g(x))\). To compare the values at the critical points, we evaluate the differences \(p(x, p_1(x)) - p(x, p_2(x)) = g(x)(p_1(x) - p_2(x))^4, p(x, p_3(x)) - p(x, p_2(x)) = (1 + g(x))/(1 - 3g(x))^2(p_1(x) - p_2(x))^4/16, p(x, p_3(x)) - p(x, p_1(x)) = (1 + g(x))/(1 + 3g(x))^3(p_1(x) - p_2(x))^2/16\). The proof follows by evaluating the signs of the Hessian and the differences at the critical points for \(g(x)\) within the intervals \((-\infty, -1), (1, -1, -1), (1 - 1/3, 0), (0, 1/3), (1/3, 1), (1, \infty)\), see Table 1. Note that \(p_3\) is an auxiliary polynomial used in the proof rather than the value of \(f\) on a subset of \(X\).

**Example 2.** In \cite{18} Example 1] a degree 8 polynomial \(arg\min\) model was described for the sign function \(f(x)\) which is equal to \(-1\) if \(x \in (-1, 0)\) and \(+1\) if \(x \in (0, 1)\). In this case \(g(x) = x, p_1(x) = +1\) and \(p_2(x) = -1\) and the construction of the proof of Lemma 2.1 yields the degree 4 polynomial \(arg\min\) model \(p(x, y) = (y + 1)^2(y - 1)^2 + 4xy(y^2 - 3)\) on \(X = [-1, 1]\), see Figure 1. Note that an even simpler \(arg\min\) model of the sign function on \(X = (-1, 1)\) is \(p(x, y) = -xy\) for \(Y = [-1, 1]\). Similarly to Example 1 the choice of domain and image sets \(X, Y\) plays here a key role.

**Example 3.** The indicator function of the bivariate unit disk \(\{x \in \mathbb{R}^2 : x_1^2 + x_2^2 \leq 1\}\) can be modeled exactly on \(X := \{x \in \mathbb{R}^2 : x_1^2 + x_2^2 \leq 2\}\) with the degree 5 polynomial \(arg\min\) of \(p(x, y) = y^2((y - 1)^2 + (1 - x_1^2 - x_2^2)(3 - 2y))\) obtained by letting \(p_1(x) = 0, p_2(x) = 1, g(x) = 1 - x_1^2 - x_2^2\) in the construction of Lemma 2.1.

---

\(^1\)A semi-algebraic function is such that its graph is described by a finite union of a finite intersection of sets defined by polynomial equations and inequalities.
3. Sample-based formulation

3.1. Notation and definitions. Let $\mathbb{R}[x, y]$ denote the ring of polynomials in the variables $x \in \mathbb{R}^n$ and $y \in \mathbb{R}$, and $\mathbb{R}[x, y]_d$ its subset of polynomials of total degree at most $d$. A polynomial $p$ is a sum of squares (SOS) if it can be written as $\sum_k p_k^2$ for finitely many polynomials $p_k$. The convex cone of all SOS polynomials of degree at most $d$ in the variable $x$ is denoted by $\Sigma_d[x]$.

3.2. Nonnegativity of univariate polynomials on an interval. Certificates of non-negativity of univariate polynomials will play a key role in our approach. The following result whose second part is due to F. Lukács is classical (see, e.g., [23] for a discussion).

**Theorem 3.1.** A univariate polynomial $q \in \mathbb{R}[y]$ of degree $d$ is nonnegative on $\mathbb{R}$ if and only if $q \in \Sigma_d[y]$. A univariate polynomial $q \in \mathbb{R}[y]$ of degree $d$ is nonnegative on the interval $[a, b] \subset \mathbb{R}$ if and only if

\[
q = \sigma_0 + \sigma_1(b - y)(y - a), \quad \sigma_0 \in \Sigma_d[y], \quad \sigma_1 \in \Sigma_{d-2}[y], \quad d \text{ even},
\]

\[
q = \sigma_0(y - a) + \sigma_1(b - y), \quad \sigma_0 \in \Sigma_{d-1}[y], \quad \sigma_1 \in \Sigma_{d-1}[y], \quad d \text{ odd}.
\]

It is a simple observation that a polynomial $\sigma$ belongs to $\Sigma_d$ (for $d$ even) if and only if there exists a positive semi-definite matrix $W \succeq 0$ such that $\sigma(y) = v_{d/2}(y)Wv_{d/2}(y)$, where $v_{d/2}$ is a basis of $\mathbb{R}[y]_{d/2}$, e.g., $v_{d/2} = [1, y, y^2, \ldots, y^{d/2}]$. Therefore the nonnegativity of $q \in \mathbb{R}[y]$ on $\mathbb{R}$ or $[a, b]$ is equivalent to the feasibility of a semidefinite programming (SDP) problem. Observing that the conditions in Theorem 3.1 are affine in the coefficients of $q$, we conclude that one can also optimize over the set of polynomials (of fixed degree) nonnegative over $[a, b]$ using SDP.

3.3. A numerical scheme. Given a function $f : \mathbb{R}^n \to Y$ with $Y = [a, b] \subset \mathbb{R}$ sampled at points $(x_i, y_i)_{i=1}^N$ with $y_i = f(x_i)$, we wish to construct an approximation $\hat{f}_d$ of the form

\[
\hat{f}(x) = \arg\min_{y \in Y} p(x, y),
\]
where \( p \in \mathbb{R}[x, y] \) is a polynomial to be determined. The set \( Y \subset \mathbb{R} \) serves as a priori information on the range of \( f \). If no such information is available, we set \( Y = \mathbb{R} \) (see Remark 3.3 for more details).

Throughout this section we assume that the argmin is unique. If this is not the case, a tiebreaker rule has to be applied (e.g., one can consider the min of the argmin). Since monomials not containing \( y \) do not influence the argmin, we use the parametrization of \( p \) as

\[
(3.2) \quad p(x, y) = \sum_{k=1}^{d_y} h_k(x) y^k,
\]

where \( h_k \in \mathbb{R}[x]_{d_x} \) are polynomials of total degree at most \( d_x \) to be determined. In order to find \( h_k \), we propose to solve the following convex optimization problem parametrized by \( d_x, d_y, d_\gamma \in \mathbb{N} \) and \( \alpha > 0 \):

\[
(3.3) \quad \min_{\gamma \in \mathbb{R}[x,y]_{d_y}, \ (h_k \in \mathbb{R}[x]_{d_x})_{k=1}^{d_y} \ } \int_{X \times [a,b]} \gamma(x, y) \, dx \, dy \\
\text{s.t.} \quad p(x_i, y) - p(x_i, y_i) + \gamma(x_i, y_i) - \alpha(y - y_i)^2 \geq 0, \ \forall y \in [a, b], \ i = 1, \ldots, N \]

\[
\gamma(x_i, y_i) \geq 0, \quad i = 1, \ldots, N,
\]

where \( p \) is parametrized using \( h_k \) as in (3.2). The rationale behind (3.3) is as follows: If \( \gamma(x_i, y_i) = 0 \), then \( p(x_i, y) - p(x_i, y_i) \geq \alpha(y - y_i)^2 \) for all \( y \in Y = [a, b] \) and hence \( y_i = \arg\min_{y \in Y} p(x_i, y) \), which means \( \hat{f}(x_i) = y_i \). Therefore, if \( \gamma(x_i, y_i) = 0 \) for all \( i = 1, \ldots, N \) we get an exact interpolation of all data points. This, however, cannot be achieved in general in which case \( \gamma(x_i, y_i) > 0 \) for some \( i \); the polynomial \( \gamma \) therefore acts as a slack variable and is minimized in the objective function. An alternative to using a polynomial slack variable is to assign one slack variable \( \gamma_i \in \mathbb{R}^+ \) to each of the constraints; here we chose to use the polynomial slack variable in order to make the number of decision variables of (3.3) independent of the number of samples \( N \), which facilitates the analysis of the generalization error in Section 3.4.

We also note that if the objective function cannot be evaluated in closed form (e.g., if the moments of the Lebesgue measure over \( X \times [a, b] \) are not known or too costly to compute), the integral can be replaced by an approximation computed from the available data

\[
(3.4) \quad \frac{1}{N} \sum_{i=1}^{N} \gamma(x_i, y_i).
\]

The optimization problem (3.3) translates to SDP by equivalently reformulating the first constraint using Theorem 3.1. For brevity, we state it explicitly only for \( d_y \) even (the difference for \( d_y \) odd is the same as in Theorem 3.1):

\[
(3.5) \quad \min_{\gamma \in \mathbb{R}[x,y]_{d_y}, \ (h_k \in \mathbb{R}[x]_{d_x})_{k=1}^{d_y}, \ \ (\sigma_{0,i}, \sigma_{1,i})_{i=1}^{N} \ } \int_{X \times [a,b]} \gamma(x, y) \, dx \, dy \\
p(x_i, y) - p(x_i, y_i) + \gamma(x_i, y_i) - \alpha(y - y_i)^2 = \sigma_{0,i} + \sigma_{1,i} (b - y)(y - a), \ i = 1, \ldots, N \\
\sigma_{0,i} \in \Sigma_{d_y}[y], \sigma_{1,i} \in \Sigma_{d_y-2}[y] \\
\gamma(x_i, y_i) \geq 0, \quad i = 1, \ldots, N.
\]

The problem (3.5) readily translates to SDP and it can be solved using off-the-shelf solvers such as MOSEK or SeDuMi.
Lemma 3.5. The following result bounds the error on data points of any feasible solution to (3.3) and (3.5).

Remark 3.4. We remark that with \( \alpha > 0 \) the argmin in (3.7) is unique on a given data point \( x_i \) provided that \( \gamma(x_i, y_i) = 0 \) (i.e., there is a zero error on the data point). Outside of the data set, we cannot guarantee the uniqueness of the argmin in which case a tiebreaker rule must be applied (e.g., taking the min of the argmin). Importantly, the results below are independent of whether the argmin is unique or not since they apply to the entire set of minimizers.

The following result bounds the error on data points of any feasible solution to (3.3) and (3.5).

Lemma 3.5 (Error on data points). Let \( p, \gamma \) and \( \alpha \) be feasible in (3.3) or (3.5) and let

\[ z_i \in \arg \min_{y \in [a, b]} p(x_i, y). \]

Then we have

\[ |z_i - y_i| \leq \sqrt{\frac{\gamma(x_i, y_i)}{\alpha}} \]

and therefore

\[ |\hat{f}(x_i) - f(x_i)| \leq \sqrt{\frac{\gamma(x_i, y_i)}{\alpha}} \]

for \( i = 1, \ldots, N \).

Proof. Let \( (x_i, y_i) \) be fixed. Observe that for any \( z_i \in \arg \min_{y \in [a, b]} p(x_i, y) \), we have \( p(x_i, z_i) - p(x_i, y_i) \leq 0 \). Therefore we have by the first constraint of (3.3) or (3.5)

\[ \gamma(x_i, y_i) - \alpha(z_i - y_i)^2 \geq p(x_i, z_i) - p(x_i, y_i) + \gamma(x_i, y_i) - \alpha(z_i - y_i)^2 \geq 0. \]

Therefore

\[ |z_i - y_i| \leq \sqrt{\frac{\gamma(x_i, y_i)}{\alpha}}. \]

The last statement of the lemma follows by the facts that \( \hat{f}(x_i) \in \arg \min_{y \in [a, b]} p(x_i, y) \) with \( p \) optimal in (3.3) and (3.5) and \( y_i = f(x_i) \). \( \Box \)
3.4. Generalization error. In this section we study the generalization error of the argmin estimator in a probabilistic setting. We assume that the samples \( x_i, i = 1, \ldots, N \), are independent and identically distributed, drawn from a probability distribution \( \mathbb{P} \) on \( X \) that is unknown to us. We study the generalization error using the tools of scenario optimization, which allows for analysis with minimal underlying assumptions on \( f \). The generalization bounds obtained have no explicit dependence on the dimension of the ambient space \( n \) and on regularity of \( f \). They depend only on the number of decision variables in (3.3), which, however, may depend implicitly on \( n \).

We first observe that Problem 3.3 can be equivalently rewritten in the form

\[
\min_{\theta \in \mathbb{R}^{n_{\theta}}} c^\top \theta \\
\text{s.t. } \inf_{y \in [a, b]} \left\{ p_{\theta}(x_i, y) - p_{\theta}(x_i, y_i) + \gamma_{\theta}(x_i, y_i) - \alpha(y - y_i)^2 \right\} \geq 0, \quad i = 1, \ldots, N \\
\gamma(x_i, y_i) \geq 0, \quad i = 1, \ldots, N,
\]

where \( \theta \in \mathbb{R}^{n_{\theta}} \) gathers all the decision variables of (3.3), i.e., the coefficients of \( (h_k)_{k=1}^{d_y} \) and \( \gamma \), and \( c \in \mathbb{R}^{n_{\theta}} \) is a constant vector such that \( c^\top \theta = \int \gamma \, dx \, dy \).

Problem (3.6) can be rewritten as

\[
\min_{\theta \in \mathbb{R}^{n_{\theta}}} \theta^\top c \\
\text{s.t. } \theta \in \bigcap_{i=1}^{N} \Theta_i,
\]

where the set \( \Theta_i \) is defined by

\[
\Theta_i := \left\{ \theta \mid \inf_{y \in [a, b]} \left\{ p_{\theta}(x_i, y) - p_{\theta}(x_i, y_i) + \gamma_{\theta}(x_i, y_i) - \alpha(y - y_i)^2 \geq 0 \right\}, \quad \gamma_{\theta}(x_i, y_i) \geq 0 \right\}.
\]

We also define

\[
\Theta_x := \left\{ \theta \mid \inf_{y \in [a, b]} \left\{ p_{\theta}(x, y) - p_{\theta}(x, f(x)) + \gamma_{\theta}(x, f(x)) - \alpha(y - f(x))^2 \geq 0 \right\}, \quad \gamma_{\theta}(x, f(x)) \geq 0 \right\}.
\]

We observe that (3.7) is the so-called scenario counterpart of the robust optimization problem

\[
\min_{\theta \in \mathbb{R}^{n_{\theta}}} \theta^\top c \\
\text{s.t. } \theta \in \bigcap_{x \in X} \Theta_x.
\]

In other words, the feasible set in (3.7) is a sub-sampled version of the feasible set of (3.8), where only \( N \) constraints, drawn independently, are enforced. Crucially, we remark that both \( \Theta_i \) and \( \Theta_x \) are convex and so are the feasible sets of (3.7) and (3.8). With these notations, we can state the following theorem:

**Theorem 3.6.** Let \( n_{\theta} \) denote the number of decision variables in (3.7). Suppose that \( \epsilon \in (0, 1) \), \( \delta \in (0, 1) \) and \( N \in \mathbb{N} \) are chosen such that

\[
\sum_{k=0}^{n_{\theta}-1} \binom{N}{k} \epsilon^k (1 - \epsilon)^{N-k} \leq \delta
\]

or

\[
N \geq \frac{1}{\epsilon} \left( n_{\theta} - 1 + \ln \frac{1}{\delta} + \sqrt{2(n_{\theta} - 1) \ln \frac{1}{\delta}} \right)
\]
hold \((3.10)\) is a sufficient condition for \((3.9)\). Let \((p, \gamma)\) be an optimal solution to \((3.5)\) with \(N\) iid samples from a probability distribution \(P\) on \(X\) and denote
\[\gamma_{\text{max}} := \sup_{(x,y) \in X \times [a,b]} \gamma(x,y).\]

Then with probability at least \(1 - \delta\) (taken over the sample \(x_1, \ldots, x_N\) with joint distribution \(P \otimes \ldots \otimes P\), we have
\[(3.11)\]
\[\mathbb{P}\left(\{x \in X : |\hat{f}(x) - f(x)| \leq \sqrt{\frac{\gamma_{\text{max}}}{\alpha}}\right) > 1 - \epsilon,\]
where \(\hat{f}(x)\) is any measurable selection satisfying \(\hat{f}(x) \in \text{Argmin}_{y \in Y} p(x, y)\).

**Remark 3.7.** We remark that if the points \(x_i\) are sampled uniformly in \(X\), the probability in \((3.11)\) is nothing but the normalized Lebesgue measure on \(X\).

**Remark 3.8** (Parameter choice). Theorem \(3.6\) can be used as a guiding tool for selecting the parameters \(d_x, d_y\). Specifically, these can be increased incrementally until a desired accuracy measured by \(\gamma_{\text{max}}\) is obtained. This is especially appealing when the degree of \(\gamma\) is zero (i.e., \(\gamma\) is a real number) in which case the value of \(\gamma_{\text{max}}\) is readily available. Otherwise, this value can be upper-bounded using the moment-sum-of-squares hierarchy \([16]\) or other methods providing rigorous bounds on the range of a polynomial.

**Proof of Theorem 3.6.** Any optimal solution \((p, \gamma)\) of \((3.5)\) induces an optimal solution \(\theta\) to \((3.7)\) and vice-versa. Given such an optimal solution, \([7\), Theorem 1\] asserts that if \((3.9)\) holds, then with probability at least \(1 - \delta\)
\[\mathbb{P}\left(\{x \mid \theta \notin \Theta_X\}\right) \leq \epsilon\]
or equivalently
\[\mathbb{P}\left(\{x \mid \theta \in \Theta_X\}\right) > 1 - \epsilon.\]
Using the definition of \(\Theta_X\), this implies that
\[\mathbb{P}(A) > 1 - \epsilon,\]
where
\[A := \{x \in X \mid \inf_{y \in [a,b]} \{p(x, y) - p(x, f(x)) + \gamma(x, f(x)) - \alpha(y - f(x))^2 \geq 0\}\}.

Given any \(x \in A\) and taking \(\hat{f}(x) \in \text{arg min}_{y \in [a,b]} p(x, y)\), we have
\[\gamma(x, f(x)) - \alpha(\hat{f}(x) - f(x))^2 \geq p(x, \hat{f}(x)) - p(x, f(x)) + \gamma(x, f(x)) - \alpha(\hat{f}(x) - f(x))^2 \geq 0,\]
where we used the fact that \(p(x, \hat{f}(x)) - p(x, f(x)) \leq 0, \hat{f}(x) \in [a, b]\) and that \(x \in A\). It follows that
\[\left(\hat{f}(x) - f(x)\right)^2 \leq \frac{\gamma(x, f(x))}{\alpha} \leq \frac{\gamma_{\text{max}}}{\alpha}\]
for all \(x \in A\). Taking square roots and recalling that \(\mathbb{P}(A) > 1 - \epsilon\), we obtain the result. The condition \((3.10)\) is a sufficient condition for \((3.9)\) derived in \([1\), Corollary 1\].

**Remark 3.9.** When the integral in the objective function \((3.5)\) is replaced by its empirical average \((3.4)\) computed from the same data set that is used to enforce the constraints, it is currently unknown whether the generalization bound of Theorem 3.6 remains valid \([8]\). A simple remedy is to use an independent sample for the objective and for the constraints, for example by splitting the data set in two.
3.5. Beyond polynomials. In this section we briefly discuss how the proposed method extends to approximants of the form

$$\hat{f}(x) = \arg\min_{y \in Y} p(x, y),$$

where $p$ is not necessarily a polynomial. The key observation to make is that when parametrizing $p$ as

$$p(x, y) = \sum_{k=1}^{d_y} h_k(x)y^k,$$

(3.12)

the functions $h_k$ appear in (3.3) and (3.5) only via their evaluations at the data points $x_i$. Therefore, parametrizing each $h_k$ as $h_k(x) = \sum_{i=1}^{n_k} c_{i,k} \beta_{k,i}(x)$, where $\beta_{k,i}$ are possibly non-polynomial basis functions, the optimization problem (3.5) remains a semidefinite programming problem with the decision variables $c_{i,k} \in \mathbb{R}$ and the coefficients of $\gamma$. The function $\gamma$ can be parametrized by non-polynomial basis functions in $(x, y)$ since only evaluations of $\gamma$ at the samples $(x_i, y_i)$ appear in (3.5).

If a non-polynomial parametrization of $p$ in $y$ was sought, one would have to resort to certificates of nonnegativity for the given function classerss akin to Theorem 3.1. Currently, this is well understood for trigonometric polynomials [11] but we envision broader function classes may be considered, given the univariate nature of the nonnegativity certificate required in (3.5) which is significantly less challenging than its multivariate counterpart.

4. Numerical examples

In this section we present several examples demonstrating the effectiveness of the polynomial argmin data structure for regression of functions possessing discontinuities. All examples were solved on a MacBook Air 1.2 GHz Quad-Core Intel Core i7 with 16GB RAM, MOSEK SDP solver. The problems were modeled using Yalmip [21]. The range of all functions was normalized to $Y = [-1, 1]$ and the parameter $\alpha$ was taken to be 0.01 in all examples. The parameters that vary in the examples are $d_x$ and $d_y$ in the parametrization of $p$ in (3.2) (i.e., $d_x$ and $d_y$ are the degrees of $p$ in $x$ and $y$ respectively). Matlab prototype codes reproducing the numerical experiments can be downloaded from https://homepages.laas.fr/henrion/software/polyargmin

4.1. Univariate: Approximation of discontinuous functions. We start by showing the effectiveness of the method on four discontinuous functions depicted in Figure 2 alongside their polynomial argmin approximations. The functions are

$$f_1 = \begin{cases} -1, & x \in [-0.75, 0.75] \\ 1, & x \in [-1, -0.75) \cup (0.75, 1] \end{cases}, \quad f_2 = \begin{cases} -1, & x \in [-0.75, -0.25] \cup [0.25, 0.75] \\ 1, & x \in [-1, -0.75) \cup (-0.25, 0.25) \cup (0.75, 1] \end{cases}.$$

$$f_3 = x^2 f_1, \quad f_4 = \sin(2x) f_1.$$

In each case we used 200 data points sampled uniformly at random in $[-1, 1]$ and solved (3.5). We observe a remarkably precise recovery of the discontinuous functions. In (3.2), the minimal degrees $d_x$ and $d_y$ required to obtain an approximation of this accuracy are reported in the figure. For comparison, in Figure 3 we depict the performance on the same task with a neural network with five hidden layers with 20 neurons per layer with the hyperbolic tangent activation functions, trained using Matlab’s neural network toolbox with gradient descent; these parameters were selected by manual hyperparameter tuning.
4.2. **Univariate: Parameter dependence.** Here we investigate the dependence of the approximation quality on $d_x$ which is the degree of the polynomials $h_k$ parametrizing the polynomial $p$ in (3.2). We do so on the function from Eq. (66) in [19] that possesses 7 discontinuities. For data, we use two hundred equidistantly spaced samples in the interval $[-1, 1]$. The results are depicted in Figure 4. As expected the approximation quality improves as the degree of $h_k$ increases, obtaining a very precise accuracy for $\text{deg } h_k = 7$. For comparison, Figure 5 depicts also the results with a neural network approximation.

![Figure 2](image.png)

**Figure 2.** Polynomial argmin approximations of different functions with discontinuities.

4.3. **Univariate: Challenging continuous functions.** For completeness we briefly report results for approximation of continuous functions. We do so on two functions. The first one is $f(x) = \sqrt{|\sin x|}$ which is a transcendental function with Hölder exponent 1/2 whose derivative grows unbounded near the origin. The second one is the Runge function $f(x) = (1 + 25x^2)^{-1}$ which is a smooth function that exhibits the Runge phenomenon (oscillations near the boundary) when approximated by polynomials through interpolation. The results are depicted in Figure 6. As in the previous examples, we observe an accurate fit and no oscillations with low degrees of $p$ in $x$ and $y$.

4.4. **Bivariate: Approximation of discontinuous functions.** On Figure 7 we represent the chebfun2 approximation to the indicator function$^2$ of a bivariate disk

$$
\mathbb{I}\{x \in \mathbb{R}^2; ||x|| \leq 1/2\}
$$

---

$^2$The indicator function of a set is equal to one on the set and zero outside.
obtained with the following chebfun \cite{10} commands:
[x1,x2]=meshgrid(linspace(-1,1,100));
plot(chebfun2(double(x1.^2+x2.^2<=1/4)));
We observe that the approximation is corrupted by the typical Gibbs phenomenon encountered when approximating a discontinuous function with polynomials \cite[Chapter 9]{24}, namely large oscillations near the discontinuity set.

On Figure\ref{fig:8} we demonstrate the performance of our argmin approximation on this indicator function. For data, we chose one thousand randomly sampled points in $[-1,1]^2$. Contrary to the Chebyshev polynomial approximation in Figure\ref{fig:7} we observe no Gibbs phenomenon and far better accuracy of the approximation despite a more parsimonious parametrization. Indeed, we used degrees $d_y=6$ and $h_k=6$ whereas the Chebyshev polynomial approximation in Figure\ref{fig:7} is of degree 100.

On Figure\ref{fig:9} we approximate the more challenging weighted sum of indicator functions of three disks
\begin{align*}
\mathbb{I}\{\|x\|\leq 1/2\} + \frac{1}{2}\mathbb{I}\{\|x-[3/4,3/4]\|\leq 1/4\} + \frac{1}{2}\mathbb{I}\{\|x+[3/4,3/4]\|\leq 1/4\}.
\end{align*}

With the same parameters as in the single disk example we observe a perfect match of our polynomial argmin approximation.
5. Discussion and Conclusion

We have presented a simple method based on the argmin of a polynomial for approximation of discontinuous functions. The approach is model-free and mesh-free in the sense that it does not require prior knowledge about the function being approximated as it works only with samples of its values. It is grounded in powerful tools from univariate sum of squares optimization, hence based only on a very specific class of convex semidefinite programming, and so it is simple to use. It shows a great promise in numerical examples and we believe that it can become a valuable tool in data analysis. We have also proved that exact recovery is possible on certain examples of discontinuous functions and have provided theoretical analysis of in-sample and out-of-sample error in a probabilistic setting. In the argmin approach [18] based on the Christoffel-Darboux polynomial, such an exact recovery is not possible in general as an $\varepsilon$-regularization term is introduced to guarantee that the associated moment matrix is non-singular. In addition, the size of the moment matrix to invert strongly depends on the dimension of data while in our optimization-based approach, the size and the number of resulting matrices to be positive semidefinite does not depend on the dimension of the data (their number is linear in the sample size).

While we have used general purpose semidefinite solvers to construct our argmin approximants, more efficient approaches can be envisioned. Indeed our formulation boils down to optimization over the cone of univariate non-negative polynomials, a very specific class of semidefinite optimization problems. For example, non-symmetric solvers may perform faster on these problems [22]. Another
Figure 5. Polynomial argmin approximation of a function with 7 discontinuities for different values of the degree of $h_k$, $k = 1, \ldots, 6$ in comparison with a neural network.

Figure 6. Polynomial argmin approximations of two continuous functions with $d_x = 4$, $d_y = 4$. Left: transcendental function with unbounded derivatives near the origin. Right: Runge function.

An option could be to bypass numerical optimization and use tailored numerical linear algebra as in [20].
An additional interesting feature of the approximant is that its evaluation at a given point $x \in X$ reduces to finding the global minimum of a univariate polynomial on an interval, which can be done efficiently e.g. by matrix eigenvalue computation. A numerically stable algorithm is described in [5, Section 7] and implemented in the roots function of the chebfun package [10]. It is based on the application of the QR algorithm for finding the eigenvalues of a balanced companion matrix constructed by evaluating the polynomial at Chebyshev points.

This paper is a first step that introduces the argmin approximant and illustrates its promising potential on non trivial numerical examples. We hope that it could inspire some further developments. In particular, we have left open the question of optimal rates of convergence of the argmin approximant or more generally its worst-case performance when considering pre-defined classes of
functions to approximate, e.g. in terms of the manifold width discussed in [9], which is a generalization of the classical Kolmogorov width. Based on Section 2.1, it is clear that the rates are at least as good as those of polynomial approximation whenever the degree of $p$ in $y$ is at least two. However, we conjecture that the rates are better for discontinuous functions.

As a final remark, the main goal of the paper is to introduce a new tool for function approximation with remarkable properties in the traditional noiseless setting when exact data is available. Of course, to validate its potential and efficiency in the more general setting of statistical learning where data can be corrupted by noise (in the $x$ and/or the value $f(x)$), a further detailed analysis is needed but beyond the scope of the present paper. We believe that relations to the max-margin support vector machine [27, 4] could facilitate this analysis.

6. ACKNOWLEDGEMENT

The authors would like to thank Francis Bach for pointing out the links to max-margin support vector machines.
