Point Group (PG) symmetries play a fundamental role in many aspects of theoretical chemistry and computational materials science. With the objective to automatize the search of PG symmetry operations of generic atomic clusters, we present a new algorithm called Symmetry Operation FINDER (SOFI). SOFI addresses the problem of identifying PG symmetry by framing it as a degenerate shape-matching problem, where the multiple solutions correspond to distinct symmetry operations. The developed algorithm is compared against three other algorithms dedicated to PG identification, on a large set of atomic clusters. The results, along with some illustrative use cases, showcase the effectiveness of SOFI. The SOFI algorithm is released as part of the IRA library, accessible at <https://github.com/mammasmias/IterativeRotationsAssignments>.

I. INTRODUCTION

In the rise of quantum-chemistry and first-principle methods, the identification of Point Group (PG) symmetry has been a necessary step to effectively downsize the numerical problem and reduce the cost of simulations. Besides the computational accelerations made possible by exploiting the symmetry, the presence and identification of a PG symmetry in a molecule, or rather a cluster, or a defect, can be used to address the fundamental properties of its electronic ground, and excited states¹. Assigning symmetry label to each state (i.e. vibrational or electronic), is desirable to connect to group theory, which is the formal context where PG symmetries are described. If the symmetry is assigned to all relevant quantum (eigen)states, group theory can be applied to specific quantum-mechanical operators to understand which matrix elements are expected to vanish based on symmetry rules. This is extremely useful for example in molecular spectroscopy: depending on the operator governing the interaction term, the symmetry-based *selection rules* will provide information on which transitions will actually be forbidden^{2,3}.

As the identification of PG symmetry is not a new problem, the computational community has made numerous attempts to automatize it. Typically, quantum chemistry software and some molecular builders/editors include capabilities related to the symmetries of the system (i.e. automatic identification, symmetrization of structure). The algorithmic approaches to identify the PG may vary based on how the atomic structures are handled, and the way symmetry elements are utilised/exploited within the software framework. Despite the fundamental nature of PG symmetries and the broad use of related algorithms, there seem to be relatively few standalone libraries devoted to their identifi-

cation. Moreover, it is often very difficult to trace which PG identification algorithm (and/or library) is integrated into the larger software environment, as the information is often poorly, or not at all documented. Many well-known quantum chemistry packages already date back to several years ago, when the modularity in programming was not necessarily a priority, so each developing group has created an "ad-hoc" method plugged into the code, often poorly updated through the years. For example by inspecting NWchem source code⁴ one can find a collection of old Fortran routines apparently written in the 90s, used for identifying symmetries. Besides, proprietary codes do not necessarily share information about their algorithm choice, even if some initiatives are more transparent, for example the IQmol builder⁵, which uses, and references the SymMol⁶ algorithm in its documentation.

In the subsequent paragraph we highlight a handful of approaches for the identification of PG symmetry, which have been devised as standalone algorithms/libraries, with some of them presently integrated into larger quantum chemistry codes, and/or computational "toolboxes".

The PG symmetry of a structure can be identified in several ways. A relatively common strategy, used in several available approaches, is to first find the principal axis of symmetry, and then test for possible operations along other axes in relation to the principal axis. The principal axes could be identified straight-forwardly by relying on the properties of the principal moments and axes of the inertia tensor, as done in SymMol⁶, and Symmetrizer⁷ software. Relying on the inertia tensor can however be problematic, since its principal axes can be ambiguous in some specific cases (spheroidal shapes). Alternatively, certain properties of the atomic structure itself (atomic positions, midpoints between atoms, etc.) can be used to identify the axes of symmetry, such as employed in SYMMAPS⁸, and SYVA⁹ software. Another idea is to partition the atomic structure into sets of symmetry-equivalent atoms, and search for symmetries within those

^{a)}Electronic mail: miha.gunde@gmail.com

sets. The partitioning can be done through the inspection of the distance matrix of the structure, such as in libmsym¹⁰, while the search for symmetries is conducted based on the properties of the inertia tensor of each equivalence set¹¹, and the PG of the entire structure is the subset of the symmetry operations common to all partitions. Some approaches based on arguments from graph theory also exist^{12,13}.

It is also common for PG-identification software to implement some other capabilities, such as precise symmetrization of structures^{7,9}, or similar, which can be thought of as extensions to the fundamental task of identifying the PG symmetry elements of a structure.

In the interest of our discussion and the algorithm we propose, we now briefly recall some fundamental notions of PG symmetry. If θ is a specific symmetry operation, which is an element of the PG of an atomic structure A , the equation:

$$A' \leftarrow \theta A, \quad (1)$$

represents the application of symmetry operation θ on structure A , which results in a symmetry-transformed structure A' . By definition of symmetry operations, A and A' are equivalent up to a permutation of atomic indices P_A :

$$A' = P_A A, \quad (2)$$

where P_A is a permutation matrix, which is unique for a given operation θ . Then, the relation:

$$P_A A = \theta A. \quad (3)$$

holds for any and every symmetry operation θ of the structure A . Each element (symmetry operation) of the PG of structure A corresponds to a unique solution of Eq. (3), in the form of a pair $\{\theta, P_A\}$.

It can be observed that the Eq. (3) is equivalent to the shape matching problem of two exactly congruent (equivalent) structures A and B , as:

$$P_B B = \mathbf{R} A + \mathbf{t}, \quad (4)$$

where \mathbf{R} is an orthonormal transformation matrix, and \mathbf{t} is a translation vector. By comparing Eq. (3) to Eq. (4), we see that \mathbf{R} is replaced by a symmetry operation θ , and the translation \mathbf{t} vanishes. When solving the general shape matching problem of Eq. (4), only one solution (the optimal one) is sought, whereas in the case of PG identification in Eq. (3), the set of all degenerate solutions represents the set of all possible symmetry operations of structure A . Finding the PG of a structure can therefore be addressed as a "degenerate" shape matching problem.

In practice, the "degeneracy" of these solutions is never exact, due to numerical limitations, or distortions in the atomic positions within the structure. An interpretation of "degeneracy" is thus needed, in terms of a threshold, such that all solutions within a given threshold are considered equivalent, degenerate. By the tuning of such

threshold, the notion of inexact symmetries can be covered.

In this work, we present the Symmetry Operation FINDER (SOFI) algorithm, and its implementation as a standalone library, aimed at solving the general problem of PG symmetry identification, in a way that is independent of specific properties of the atomic structure. SOFI finds the PG symmetry operations in the form of 3×3 matrices, and the corresponding permutations of atomic indices. The working principle of SOFI is fundamentally based on ideas and arguments of the shape-matching algorithm IRA^{14,15}. In contrast to other algorithms from the literature mentioned earlier, SOFI does not attempt to identify any special axes of symmetry, but is instead focused directly on generating the possible symmetry operations along *any* axis. SOFI takes as input an atomic structure, and returns the list of symmetry operation matrices, written in the specific form of the original reference frame, in which the structure was input/written. As such, the matrices can directly be used without any post processing. From this point of view, SOFI is a *solver* for symmetry elements, that does not modify the input structure in any way. In order to determine the PG of a structure, a separate routine is called, taking as input the list of symmetry operation matrices. Within this routine, each symmetry operation is first associated to the axis it acts on, and labelled according to the Schoenflies notation³. The PG is then deduced by inspection of the symmetry elements, following a standard flowchart. The search for non-exact symmetries in SOFI can be tuned via a threshold parameter, whose value is directly linked to the distortions in the atomic positions of the structure. Moreover, in case of an incomplete list of elements of a PG, basic arguments of group theory can be used to find the missing elements. An incomplete list of symmetry elements can be an indicator of broken symmetries in the system, which might happen when the atomic positions get distorted in a particular way. Due to the modularity of the algorithm implementation, external conditions acting on symmetry elements can easily be implemented through custom functions. As an example of such function, the action of an external arbitrary-direction magnetic field on the PG of a structure¹⁶ is included in the code. SOFI is written in Fortran, with a C-bound Application Programming Interface (API), making it a directly interoperable library. It can be used on its own, or easily inserted into other software.

Section II describes the details of our SOFI algorithm, and the Section III gives the implementation details. In the Section IV, SOFI algorithm is compared to three other algorithms for PG symmetry identification, namely SYVA⁹, SymMol⁶, and libmsym¹⁰. The discussion in Section V provides some possibly valuable insight into technical details of the algorithm, and the limits and tuning of its maximal "resolving" power. The Section VI gives some exemplary use cases of the SOFI algorithm, and its output. Further examples can be found in the online documentation.

II. THE ALGORITHM

We approach the problem of finding PG symmetries by solving the degenerate shape-matching problem of Eq. (3), but firstly we need to address the question of the origin point.

A fixed point is a point in space which remains unchanged under transformation by an arbitrary set of orthonormal matrices. When an atomic structure is transformed by symmetry operations belonging to some PG, we can observe one or more such fixed points. The points that remain fixed under transformation by all symmetry elements of the PG are the origin points of the entire PG, while points that are fixed only for a subset of the symmetry elements are origin points of the subgroups associated to that PG. For example, the *Oh* PG has six *C4v* subgroups oriented in three different directions, each with a different origin point, while in the case of *C*-groups, all points along the primary rotation axis are fixed. However, the only point of a generic structure, which is guaranteed to always remain fixed under transformation by any orthonormal matrix or symmetry element, is the geometric center (center of geometry, arithmetic mean, centroid). Therefore, picking the geometric center of a structure as the origin point, guarantees that the algorithm will parse the full PG of the structure. Indeed, most of the available algorithms assume this choice by default. However, alternative origin points are possible. For example when searching for symmetry operations about a given atom, the origin point should be the position of that specific atom (or some other specific point of choice). SOFI is agnostic to the choice of origin, which means it will find symmetry operations about the given point. This also means the origin has to be chosen from the outside (by the user, or another application).

After the origin point has been selected and the structure shifted accordingly, the atomic structure enters the main search loop of the SOFI algorithm. The key idea of SOFI is to parse the space of orthonormal transformations, at each step construct a trial transformation, evaluate Eq. (3) with the trial transformation, and keep track of all favourable solutions. Thus, the algorithm needs two main components, as follows.

The first component is a function which will evaluate Eq. (3). The idea employed in SOFI is to transform Eq. (3) into a distance $d(P_A A, \theta A)$, which should be equal to zero when P_A and θ correspond to a solution of Eq. (3), and greater than zero otherwise. In order to compute the distance $d(P_A A, \theta A)$, we employ the Hausdorff distance function^{14,15,17} with the generic form:

$$d_H(A, B) = \max_{a \in A} \min_{b \in B} d(a, b) \quad (5)$$

where A and B are structures with atomic vectors $a \in A$, $b \in B$, and $d(a, b)$ is a Cartesian distance. The Hausdorff distance is invariant to permutations, and variant to other rigid transformations of either structure (rotation, reflection, translation). The evaluation of Eq. (3) is

thus done by computing Eq. (6).

$$d(P_A A, \theta A) = d_H(A, \theta A) \quad (6)$$

If θ is a solution of Eq. (3), then $d_H(A, \theta A) = 0$. In order to compute d_H in SOFI, we use the CShDA algorithm, introduced in Ref.¹⁴. CShDA imposes a one-to-one assignment constraint on the atoms, and returns the permutation P_A and distance d_H .

The second component of the algorithm is a way of parsing the space of orthonormal transformations (3×3 orthonormal matrices θ). This parsing should be computationally efficient, but still broad enough to identify all possible solutions of Eq. (3). In SOFI, we define the parsing of transformation space in a similar way as in IRA¹⁴, in which the orthonormal transformations (bases) are constructed directly from atomic vectors present in the structure. It follows from Eq. (3), that for each atom $i \in A$ with the atomic position a_i , there exists a unique atom $j \in A$ with the atomic position a_j , such that:

$$a_i = \theta a_j. \quad (7)$$

The Eq. (7) can be seen as operation of change of basis, from the basis β defined by a_i , to basis γ defined by a_j , written:

$$\beta a_i = \gamma a_j, \quad (8)$$

from which we see that

$$\theta = \beta^T \gamma. \quad (9)$$

Therefore, the operation θ is completely defined by two orthonormal bases, namely β and γ , which are defined by atomic positions a_i and a_j , respectively.

However, an orthonormal basis set in 3D cannot be uniquely defined from a single 3D vector. This problem is resolved by adding another atomic vector $a_{i'}$ to the definition of the basis, as follows. The first basis vector \hat{e}_1 is the normalised atomic vector a_i , the second basis vector \hat{e}_2 is the component of the atomic vector $a_{i'}$ orthonormal to \hat{e}_1 , and the third basis vector is a cross product $\hat{e}_3 = \hat{e}_1 \times \hat{e}_2$. In this way, the basis β is defined by positions of atoms i and i' , and the basis γ by positions of atoms j and j' . Due to this, SOFI is restricted to structures containing at least 3 non-collinear atoms. The same procedure for constructing an orthonormal basis is used in IRA¹⁴.

According to the preceding considerations, in order to identify any symmetry operation θ , we need to find the quadruplet of atoms $\{i, i', j, j'\}$, which construct θ by Eq. (9), such that Eq. (3) is satisfied. In order to find all possible solutions of Eq. (3), we need in turn to list all unique matrices θ that can be constructed by such quadruplets of atoms, while also satisfying $d_H(A, \theta A) = 0$ by Eq. (5). The most naive algorithm to find all symmetry operations θ is then to brute-force search over all combinations of quadruplets of atoms in A , which give $d_H = 0$. Such algorithm is constructed by four nested

DO loops over all atoms, meaning an $\mathcal{O}(N^4)$ complexity, where N is the number of atoms in the structure. We can however quickly observe that such approach contains a huge degree of redundancy, which can be greatly reduced, or even avoided, by applying the following considerations.

A. Reduce complexity I: fix one basis

The Eq. (7) holds true for a given θ , for all atoms i simultaneously. Therefore, instead of looping over all i , i' , j , and j' , we can simply select any two different atoms i and i' , and loop over only j and j' . The atoms i and i' construct the basis β , which is kept fixed throughout the search, while the basis γ constructed by atoms j and j' keeps changing, effectively constructing different trial θ operations. The argument also holds for all possible operations θ , since each true symmetry operation θ is associated to a single permutation P_A . Thus the complexity of the search algorithm is reduced to $\mathcal{O}(N^2)$.

B. Reduce complexity II: preserve distances and atomic types

A PG symmetry operation θ is a unitary transformation, meaning it preserves distances. Thus, an atom after the transformation cannot have a position which is at a different distance from the origin than it was before the transformation. Moreover, upon transformation by θ , the position of atom i is effectively replaced by the atom j , which must have the same properties as atom i . Hence atom j should possess the same atomic type, and be positioned at the same distance from the origin, as atom i . This can be translated into a simple constraint for the choice of atom j – and also j' – namely the norms of atomic vectors (distances from the origin) must be equal, $\|a_i\| = \|a_j\|$ and $\|a_{i'}\| = \|a_{j'}\|$; and the atomic types of the pairs $\{i, j\}$ and $\{i', j'\}$ must be identical (see lines 4,5 and 7,8 of Alg. 1). Thus the complexity of the search algorithm is further reduced, to $\mathcal{O}(N_i N_{i'})$, where N_i and $N_{i'}$ are the number of atoms within the same radial distance and atomic type as atom i , and atom i' , respectively.

C. Reduce complexity III: pick atoms close to origin

The numbers N_i and $N_{i'}$ are further reduced by choosing i and i' which are as close as possible to the origin (avoiding the atoms at the origin, for numerical reasons), and are of the atomic type which has the least number of equivalent atoms in that radial shell. For close-packed structures (clusters), the worst-case scenario is a structure of a single atomic type, where N_i and $N_{i'}$ are 12 (hexagonal close-packed single-crystal structure), which

means 144 possible constructions of θ by the SOFI algorithm. For some types of structures however, these numbers can be a lot higher, the extreme case being fullerene-type structures where all the N atoms are at the same distance from the origin, $N_i = N_{i'} = N$. For those structures, the use of SOFI as described and implemented in the present paper is not efficient.

D. A word about (roto-)reflections

Notice that when the bases β and γ are generated with the procedure defined earlier, the matrix θ resulting from Eq. (9) is always such that its determinant is positive, $\det(\theta) = 1$. This means our search algorithm always produces trial transformations which correspond strictly to rotations. In order to mitigate this behaviour, we systematically flip each of the three vectors for each basis γ that is generated (see line 11 of Alg. 1). As such, the resulting trial transformations include proper rotations, reflections, and roto-reflections. This slightly raises the complexity of the algorithm by a factor of 4 (one for the original γ , and additional three for each flipped axis).

E. Inexact symmetries

A structure can exhibit inexact symmetries due to disorder or inaccuracies in atomic positions, which can be purely numerical, or due to physical reasons. In any case, this disorder can cause some symmetry elements to become inexact, *i.e.* the distance $d_H(A, \theta A)$ does not reach zero, but only a local minimum. For this reason we introduce the threshold `sym_thr` into SOFI, which modifies the condition for a transformation θ to be recognised as symmetry operation of a structure A into $d_H(A, \theta A) \leq \text{sym_thr}$, which is interpreted as the maximal deviation (in units of distance) between an atom of the non-transformed structure, and its associated atom of the transformed structure, must be below the threshold. The value of `sym_thr` is an input parameter to SOFI. For the same reason of possible disorder in the atomic structure, the transformations θ which are constructed from atomic vectors by Eq. (9), can potentially become inexact (in the sense of non-zero d_H). In order to obtain as precise transformation matrices θ as possible, we introduce the concept of matrix refinement, see Sec. III and Alg. 3.

It can still happen that SOFI's parsing procedure will not identify all the symmetry operations of a structure due to such atomic disorder. In that case, arguments of fundamental group theory can be used to generate the missing symmetry operations. The most important argument is the property of group closure, which states that if $\theta_i \in G$ and $\theta_j \in G$ then also the product $\theta_i * \theta_j \in G$, where G is the point group. Therefore, after the main parsing procedure of SOFI is performed, the list of found symmetry operations can be looped through itself, and

all possible products of the operations generated, then tested for the symmetry condition on the structure, and finally included in the set accordingly. Thus if any symmetry operation has been missed by the main search algorithm for any reason, it will be found and added by this (optional) procedure.

The value given to the threshold `sym_thr` is directly linked to the level of disorder in atomic positions on the structure. Its extremal value can ultimately be related to the distance between nearest atoms in the structure, in the sense that if the value `sym_thr` is close to, or larger than that, the algorithm will accept operations that effectively exchange the positions of atoms, as valid symmetry operations. In order to avoid that, the rule of thumb is that `sym_thr` can sensibly be set to any values up to about half the distance between nearest atoms, anything beyond that should be carefully tested, and will most probably produce results that will be hard to interpret.

III. IMPLEMENTATION

The main loop of the SOFI search procedure is schematised in Alg. 1, which follows the considerations from Sec. II. Each iteration of the main loop consists of constructing a new orthonormal basis γ , and with it a new trial operation θ' . Each trial θ' is passed to the routine `try_sofi` (schematised in Alg. 2). This routine first determines if the matrix is already a known symmetry operation, and if not, computes the first $d_H(A, \theta'A)$ via the CShDA algorithm. If the first d_H is small enough, the trial θ' is considered as potential symmetry operation, and passed to the `refine` routine (schematised in Alg. 3). The `refine` routine returns a refined trial θ' and the associated $d_H(A, \theta'A)$. If this distance d_H is below the threshold `sym_thr`, the trial θ' is stored as a new symmetry operation of A . At the end of the main loop, the list of symmetry operations θ of structure A is known.

A trial matrix transformation θ' , whose action on a structure A is sufficiently close to some true symmetry operation θ , can be identified, and *refined* to correspond to the true symmetry θ , see Alg. 3. The matrix θ' is said to be sufficiently close to θ , when the distance $d_H(A, \theta'A)$ is below a given parameter value, but not zero (this value in SOFI corresponds to $5 * \text{sym_thr}$, see line 4 of Alg. 2). In this case, the permutation of atoms P_A that is returned when computing $d_H(A, \theta'A)$ with CShDA, is not exact, but can be said to be partially correct, meaning that there are at least some atoms for which the assignments are correct. This partially correct assignment can be applied to the structure A , and used as input to the well-known SVD-based algorithm described in Ref.¹⁸, which returns an optimal rotation given a fixed permutation of atoms. The small rotation ν which is found by SVD is added to the original transformation, $\theta'' = \nu\theta'$, and applied to the structure, $\theta''A$. At this point, the distance $d_H(A, \theta''A)$ and the corresponding assignments

Algorithm 1: The main search loop of SOFI, including the considerations from Sec. II A-II D. The called routine `try_sofi` is schematised in Alg. 2.

Input: structure A , threshold `sym_thr`.
Output: List of symmetry operations θ .

```

1 Select  $i$  and  $i'$  close to origin;           !! Sec II C
2  $\beta \leftarrow$  OrthonormalBasis(  $i, i'$  );    !! Sec II A
3 for  $j \in 1, N$  do
4   if(  $\text{abs}(|a_i| - |a_j|) > \text{sym\_thr}$  )cycle; !! Sec II B
5   if(  $\text{typ}(i) \neq \text{typ}(j)$  )cycle;
6   for  $j' \in 1, N$  do
7     if(  $\text{abs}(|a_{i'}| - |a_{j'}|) > \text{sym\_thr}$  )cycle;
8     if(  $\text{typ}(i') \neq \text{typ}(j')$  )cycle;
9      $\gamma \leftarrow$  OrthonormalBasis(  $j, j'$  );
10    for  $m \in 0, 3$  do
11      flip axis  $m$  of  $\gamma$ ;           !! Sec II D
12       $\theta' = \beta^T \gamma$ ; call try_sofi( $A, \theta', \text{sym\_thr}$ );
13    end
14  end
15 end
```

Algorithm 2: The schema of routine `try_sofi`. The called routine `refine` is schematised in Alg. 3.

Input: structure A , 3×3 matrix θ' , threshold `sym_thr`.
Output: Updated list of symmetry operations θ .

```

1 Compare  $\theta'$  to current list of all  $\theta$ ;
2 if(  $\theta' \in$  list )return;
3 Compute  $d = d_H(A, \theta'A)$  via CShDA algorithm;
4 if(  $d > 5.0 * \text{sym\_thr}$  )return;
5 call refine( $A, \theta', d_H$ );
6 if(  $d_H \leq \text{sym\_thr}$  )add  $\theta'$  to list;
```

P_A'' are recomputed. If P_A'' contains permutations, the cycle of SVD-CShDA is repeated. Once the new assignment does not contain any further permutation, the procedure is stopped, the refined matrix is $\theta'' = \nu\theta'$, and if $d_H(A, \theta''A) \leq \text{sym_thr}$, then the refined matrix θ'' is a true symmetry operation θ . The process is schematised in Algorithm 3.

Algorithm 3: The schema of routine `refine`.

Input: structure A , trial matrix θ' .
Output: refined matrix θ' , distance d_H .

```

1  $\theta'' \leftarrow \theta'$ ;
2  $P_A, d_H \leftarrow$  CShDA( $A, \theta''A$ );
3 for  $n \in 1, \text{max\_iter}$  do
4    $\nu \leftarrow$  SVDrotation( $A, \theta''A$ );
5    $\theta'' \leftarrow \nu\theta''$ ;
6    $P_A, d_H \leftarrow$  CShDA( $A, \theta''A$ );
7   if (no permutation in  $P_A$ ): exit loop;
8 end
9 return  $\theta'' \leftarrow \theta'', d_H$ 
```

The self-sufficient iteration scheme of Algorithm 3 is similar to the algorithm Iterative Closest Point (ICP)¹⁹, which is very well known in the computer vision community. ICP has some known pitfalls, and several proposed solutions to them²⁰. The most notable being getting stuck in local minima, or oscillating between two equivalent solutions. It should be stated that these pitfalls can in principle occur in our matrix refinement approach as well, however, they occur in situations when $d_H(A, \theta' A)$ is far from zero, and above any meaningful threshold, thus the trial transformation θ' in such situations is far from a suitable candidate for our purposes, and it is not of concern. Moreover, the number of iterations in Algorithm 3 has a hard limit at `max_iter=3`.

In order to determine the PG from a list of symmetry operations in the form of 3×3 matrices, as returned by SOFI, we have implemented a decision process based on a flowchart available in physical chemistry textbooks³. The decision tree is based on the identification and classification of specific symmetry elements. For our purpose, the simplest way of carrying it out is to employ the Schoenflies notation for the symmetry elements, in the form of $Op\ n^p$, where Op is the name of the operation (C for rotation, S for rotoreflection, I for inversion, and E for identity), n is the order of rotation, and p the multiple of rotation, for example $S\ 12^5$ corresponds to a rotoreflection with an angle of $\frac{5}{12}2\pi$. The analysis of a 3×3 matrix, and assignment of its Schoenflies label is done as described in the Appendix A. Once the list of symmetry operations is converted to the Schoenflies notation, and grouped together by the axis they act on, the decision tree to determine the PG is applied.

The SOFI software library is organized as a series of independent routines. For performing a default (full) search for PG of a structure, there is a wrapper routine which includes calls to all the needed routines. This includes shifting the structure to its geometric center before entering SOFI, and using the closure property of the groups to fully identify all symmetry operations (see Sec. IIE). A workflow for more specialized tasks can be constructed as-desired from the routines included in the library.

The source code repository also includes an API to the main SOFI routines, which is bound to the C-namespaces via the `iso_c_binding` intrinsic Fortran module. The API is compiled into a dynamic library (file `.so`), and thus the interface routines can easily be linked and called from either Fortran or C, or imported into Python. Example programs for each of these languages are included in the repository. An appropriate Python module is also proposed, which acts as an interface to the C-bound routines in the dynamic library, through the `ctypes` Python module.

IV. COMPARISON TO OTHER ALGORITHMS

The SOFI algorithm has been compared to the SYVA⁹, SymMol⁶, and libmsym¹⁰ software. The full details and results of the tests are available in the Supplementary Materials, and the associated Zenodo repository²¹ which contains all the structures, software, and scripts used in the test, and all results in plain text format. The goal of this comparison is to showcase the behaviour of SOFI in comparison to other established software.

All of the atomic structures included in our comparison test were obtained from the Cambridge Cluster Database (CCD)²². They include atomic cluster structures, where we have excluded any structures with number of atoms less than 3. The total number of structures included in the test is thus 3858, with the number of atoms varying between 3 and 380. There is only one set of structures with more than one atomic type, which has two atomic types.

The comparison tests were carried out by computing the PG of each input structure, at different values of the symmetry threshold. Changing the value of this threshold can result in the respective algorithm detecting a different number of possible symmetry operations, and hence a different assignment of the PG. The SYVA and SymMol algorithms have a single adjustable parameter for the tolerance, which, to our understanding, is more or less equivalent to the symmetry threshold `sym_thr` used in SOFI. That is, it specifies the maximal allowed displacement of any atom of the symmetry-transformed structure, with respect to the original structure. Therefore, it is possible to directly compare the results of SYVA, SymMol, and SOFI algorithms at the same value of tolerance. On the other hand, the libmsym algorithm does not have a single-valued parameter for the tolerance, but rather a set of parameters which act upon different segments of the algorithm, and it is therefore not straight-forward to compare the results. Any computation where a respective algorithm outputs an explicit message of error or failure, or the software crashes with no output, is recorded as a failure.

The values for the tolerance used in SYVA, SymMol, and SOFI were $tol = 0.001$ and $tol = 0.05$, while for libmsym we used three sets of parameters which are also used in the Avogadro software²³, where they are labelled as "default", "medium", and "loose".

To the best of our knowledge in the CCD database, the source/algorithm which was used for obtaining the listed PGs is not clearly specified. This is an issue since the claimed PG cannot be actually tested or revised. In other words, the PG assignment by CCD cannot be assumed to have a benchmarking value.

The Fig. 1 gives a correlation plot of the PGs as assigned by the different algorithms included in the test, excluding CCD. This plot has been made by combining the results of each algorithm in the test, using the value of tolerance for which that algorithm produced the least failures. These are explicitly SYVA($tol = 0.001$),

SymMol($tol = 0.05$), libmsym($tol = "default"$), and SOFI($tol = 0.05$). A point on the diagonal of the plot represents PG assignments of SOFI equal to any of the other algorithms, while an off-diagonal point represents different assignment of PGs, for the same structure. The distance of a point from the diagonal could be seen as proportional to the extent of the difference in the assignment, in terms of number of symmetry operations of a group. Similar plots of this type are available in the Supplementary Materials, resolved per each algorithm and tolerance value included in the test.

We show in the Supplementary Materials, that SOFI is fully capable of computing the PG symmetry in atomic clusters. Contrary to other algorithms in the test, there are zero cases of failure in SOFI, among all the structures and tolerance values included in the test. In all cases of disagreement between SOFI and another algorithm, SOFI is capable of finding a PG of the same order, or higher, when computed with an appropriate tolerance value.

The small differences in SYVA, SymMol, and SOFI most probably arise due to the different ways in which algorithms find the symmetry operations, or their axes. A small difference in the axis on which a symmetry element acts, can lead to a small difference in the atomic positions of the symmetry-transformed structure, which leads to a different value of distance to the original structure. When such small discrepancies lead to distance values that are comparable to the value of symmetry threshold used, they can be sufficient to cause an algorithm to detect PGs of a different (lower) order. These small variations can be observed in our tests, where in some cases SOFI detects less symmetry operations than SYVA and SymMol, however upon slight increase in the threshold, the higher-order PGs are always retrieved.

A more in-depth analysis of all the results would require a detailed inspection of the participating algorithms, and a case-to-case analysis of each result, which is well beyond the scope of the present article. Besides, our tests did not investigate the impact of the symmetry threshold in a systematic way, which makes drawing any general conclusions from this comparison test nontrivial.

The Dzugutov-mod clusters dataset was used to give some indicative timing of the algorithms. It contains 248 structures with number of atoms from 3 to 250, all of the same atomic type. The structures where an algorithm was not able to determine a PG were excluded from this measurement, since they take a disproportionate amount of time. The SYVA algorithm took 155.8 s to determine 248 PGs, SymMol took 2.1 s to determine 245 PGs, libmsym took 0.8 s to determine 245 PGs, and SOFI took 1.2 s for 248 PGs. All the timing measurements were done on single Intel Core i7-10700K processor.

FIG. 1. Compact summary of the comparison test results: The horizontal axis represents PGs as assigned by SOFI, and the vertical axis PGs assigned by any other algorithms in the test (SYVA, SymMol, libmsym). Labels of PGs are sorted by the cardinality of the groups. The points below the diagonal represent cases where SOFI assigned a PG with higher order, and values above the diagonal represent cases where SOFI assigned a PG with lower order. The color of each point represents the number of structures where that particular combination of PG assignment happened.

V. DISCUSSION

Due to the SVD-based "matrix refinement" procedure introduced in SOFI (Sec. III, Alg. 3), the axis of a symmetry element is ultimately set such that the root-mean-square distance between the original, and the symmetry-transformed structure $d_{rmsd}(A, \theta A)$ is minimized. However it should be noted that, in general, the value of θ which minimizes a distance function D , in the sense of Eq. (10),

$$\arg \min_{\theta} \{D(\theta A, A)\} \quad (10)$$

can be slightly different for different distance functions D , such as the root-mean-square d_{rmsd} , and Hausdorff distance d_H , the latter of which is used to evaluate the operations θ in SOFI by Eq. (6). This is a small inconsistency in the SOFI algorithm, and it means the value of Eq. (6) can actually *increase* slightly after the matrix refinement procedure. We have found in our tests that this is the reason for SOFI to set the axis of some symmetry operation slightly different than the other algorithms, and that leads to rare cases when SOFI needs a slightly higher value of symmetry threshold, to obtain the same PG as SYVA or SymMol. In the set of structures used in our comparison test, the usefulness of the matrix refine-

ment procedure might not be apparent, however when SOFI is used on structures with more disorder in the atomic positions, the refinement procedure is key to the recognition of proper symmetry operations.

The slowest part of the SOFI algorithm is the evaluation of the distance $d_H(A, \theta'A)$ from Eq. (5), calculated by the CShDA algorithm, which is done for each trial θ' . It would make sense to spend some computational effort in trying to lower as much as possible the number of times CShDA is computed. This can be done by recognising when a trial θ' is very similar to some already known symmetry operation θ , meaning the trial θ' can be skipped, and thus avoid computing CShDA. In order to evaluate the similarity between two orthonormal matrices, we use a simple distance function $d(\theta^a, \theta^b)$, which is a sum of the distances between the matrix elements:

$$d(\theta^a, \theta^b) = \sqrt{\sum_{i,j} (\theta_{ij}^a - \theta_{ij}^b)^2} \quad (11)$$

which can be seen as a measure of the order of rotation needed to transform θ^a into θ^b . By default, SOFI considers two orthonormal matrices, namely θ' and θ , as equal when the order of rotation needed to transform one into the other is more than 200, that is an operation C200 in the Schoenflies notation, or rotation by angle $0.005 \cdot 2\pi$. This sets the maximal limit to the resolving power of SOFI, meaning that any symmetry operation of order higher than 200 can not be recognised. This default behaviour can be changed by tuning of some internal parameters, and recompiling the code. The procedure to do that is detailed in the online documentation, available through the front page of the GitHub repository.

With this modification to SOFI, a relatively big speed-up is achieved for structures with a large number of atoms close to the origin (number N_i in Sec. IIC), where the redundancy of the search space of matrices θ is large. The very extreme example of such structure being the perfect fullerene-type structures, where all atoms are at the same distance.

The search space of highly symmetric tetrahedral, octahedral, and icosahedral PGs in particular – T , O , and I variants – can be largely redundant. In SOFI, this redundancy can be reduced by an early-termination condition, which is triggered when both of the following criteria are met: *i*) either σ or I operations are found, and *ii*) there are two or more unique C_n axes with $n \geq 3$. The two criteria are sufficient to terminate the search procedure, and directly identify the corresponding PG by the standard procedure. In principle, this condition can be ambiguous, since a group can be a subgroup of another (for instance, all T variants are subgroups of Oh). However the ambiguity is lifted by performing the combinations of symmetry elements identified at the current step of the algorithm, which are at that point extremely unlikely to be cyclic, and will thus generate the missing operations. The overhead of computing the early-termination condition is largely negligible.

The redundancy of the search space however cannot be reduced by the mentioned arguments when the number of symmetry operations is low, as for instance in $C1$, Cs , and Ci PGs. The absolute worst-case performance for the SOFI algorithm as presented in this article is thus a structure with many atoms N , all of a single atomic type, where relatively many of them are close to the origin (N_i in Sec. IIC), and a low-order PG.

VI. EXEMPLARY USES

A. Generating PG by combination of group elements

In SOFI, the assignment of PG name is done by a separate routine, which acts only on the list of operations θ . Thus, we can design a small program which reads a number of input operations, generates all possible combinations $\theta' = \theta^i * \theta^j$ in a self-consistent manner, and assigns the PG name to the final list of operations. In the present example, we use this program to confirm that the D2h and D3d groups are indeed among the subgroups of D6h. In group theory a high-symmetry PG may lose certain elements to give rise to a new PG, which is a subgroup of the former. Such descent of symmetry can be useful in certain applications. The small program of this example is included in the examples directory of the git repository: `examples/SOFI/ex_D6h_subgroup`.

The upper part of Table I lists the symmetry operations θ of some atomic structure with the D6h PG (the precise structure is not important for this example). If we take only the four operations of labels 5 and 7, and generate all possible unique combinations $\theta' = \theta^i * \theta^j$, we obtain the list of operations in the middle part of Table I. It is straightforward to verify that the obtained list of operations corresponds to D2h PG, and that all the resulting operations are in fact part of D6h, and therefore D2h is a subgroup of D6h.

Similarly, by generating all possible combinations of the four operations labelled 6 and 7 on the upper part of Table I, we obtain the list shown in the lower part of Table I, which constitutes the D3d PG, and is a subgroup of D6h. It can be verified that if we take all unique operations from the middle and lower parts of Tables I, which is 16 operations, and input them to the combinations program, we obtain back the list of 24 operations of D6h from the upper section of Table I.

B. Obtaining symmetry-equivalent configurations

The power of knowing the set of local symmetries θ is demonstrated on the example system of heptamer island on Pt(111) surface, taken from the OptBench database²⁴, shown on Fig. 2.

A particular, known displacement of the atoms from the initial structure is shown on Fig. 3 in six symmetry-equivalent variants in each panel, with the displacement

	Label	Operations θ	Axis
D6h	0	E, I	
	1	$\sigma, C_2, C_3, C_6, S_3, S_6$	0.989 -0.094 -0.109
	2	σ, C_2	-0.052 -0.939 0.339
	3	σ, C_2	-0.134 -0.330 -0.934
	4	σ, C_2	-0.022 0.648 -0.761
	5	σ, C_2	-0.112 -0.978 -0.173
	6	σ, C_2	-0.142 -0.756 -0.639
	7	σ, C_2	0.090 -0.183 0.979
D2h	0	E, I	
	1	σ, C_2	-0.112 -0.978 -0.173
	2	σ, C_2	0.090 -0.183 0.979
	3	σ, C_2	0.989 -0.094 -0.109
D3d	0	E, I	
	1	$C_3, \overline{C_3}, S_6, \overline{S_6}$	0.989 -0.094 -0.109
	2	σ, C_2	0.090 -0.183 0.979
	3	σ, C_2	-0.142 -0.756 -0.639
	4	σ, C_2	-0.052 -0.939 0.339

TABLE I. Upper part: list of operations θ of some structure with the D6h PG, grouped together by the axis they act on. The transposes of applicable operations ($\overline{C_3}, \overline{C_6}, \overline{S_3}, \overline{S_6}$) on axis 1 are omitted for clarity.

Middle part: the resulting operations of all possible combinations of four operations on axes 5 and 7 from the upper part. The PG with these operations is D2h, and all the operations are also included in D6h.

Lower part: the resulting operations of all possible combinations of four operations on axes 6 and 7 from the upper part. The PG with these operations is D3d, and all the elements are also included in D6h.

FIG. 2. Initial state configuration of the heptamer island on Pt(111) surface. Left: side view. Right: top view of the surface layer, with bonds drawn between the atoms of the island. Marked in green are the atoms of the local configuration that is used as input for SOFI.

vectors marked in cyan, each labelled Δ_j , for $j \in [1, 6]$. The displacement of the atoms by specifically these vectors actually corresponds to equivalent configurations at the saddle point of the potential energy surface (PES) of the system, the details of which are not important for the purpose of this example. By knowing only one of these displacements, say Δ_1 shown on the top left panel of Fig. 3, the other five can be generated by only using the information of local symmetry of the heptamer

island, which can be computed by SOFI.

FIG. 3. First panel (top left) shows Δ_1 in cyan, which is on other panels transformed by the set $\{\theta_j, P_j\}$, and represents saddle points of the PES equivalent by local symmetry. The top row contains the rotations of Δ_1 about the axis through the origin atom (out of plane axis), and the bottom row contains reflections of Δ_1 over three mirror planes.

In the present example, this was done by first selecting the first-neighbour local configuration around the atom at the center of the heptamer, shown in green on Fig. 2, where the set of atomic indices contained in the local configuration is labelled $[s]$, and the atom at the center of the heptamer is taken as the origin point. This local configuration was then input to SOFI as an independent atomic structure, which returns the set of six symmetry operation matrices and the corresponding permutations $\{\theta_j, P_j\}$, in relation to the desired origin. The symmetry operations are three rotations about the vertical axis through the origin atom, and three mirror reflections. The displacement $\Delta_1[s]$ on the subset of atoms $[s]$ can then be transformed by applying each matrix θ_j , followed by permutation of the vector elements P_j , to obtain the other five displacements $\Delta_j[s]$,

$$\Delta_j[s] = P_j(\theta_j \Delta_1[s]) \quad (12)$$

which correspond to the displacement vectors of Fig. 3, and bring the system to the symmetry-equivalent saddle point configurations.

The example shown in this section illustrates a procedure which exploits the list of symmetry operations, and applies them on some property of the atomic structure to obtain the symmetry-equivalent representations of that property, in this case a displacement. By analogy, such procedure can be done to any vectorial property of a structure, for which symmetry-equivalent representations exist. The symmetrization of an atomic structure is an example of such procedure (with some modifications), acting on the atomic positions.

VII. CONCLUSION

We have developed the SOFI algorithm for finding PG symmetry operations of non-periodic atomic structures, based on the IRA shape matching algorithm¹⁴. The working principle of SOFI is to cast the problem of finding PGs as a shape-matching problem of a single structure with itself, and find all the degenerate solutions. The set of these solutions corresponds to the symmetry operations of the atomic structure.

Contrary to some other algorithms, SOFI is not limited to the number of atoms that a structure can contain. It is also agnostic to the choice of the origin point, which allows the identification of symmetry operations about any chosen point/atom, not only the geometric center.

We have tested SOFI on a large set of atomic structures where symmetry identification can be challenging, such as single-element clusters and close-packed structures. The former are critical because of the large number of possible permutations of atomic indices, and the latter due to the rather homogeneous spatial distribution of atoms, which prevents simple identification of any principal axes. Both these cases are of relevance for numerical applications, for instance in processing substructures obtained from other condensed phase (periodic) simulations, whenever a local symmetry assignment is required for clusters or slabs, and hence where an automatic assignment of symmetry is highly desirable. Due to the way SOFI parses through the space of possible operations, it can be advantageous in such critical cases.

We have compared the results of our SOFI algorithm to three other algorithms for PG identification from the literature, namely SYVA, SymMol, and libmsym, at two different values of the symmetry threshold. The results are given in a statistical manner that shows the general behaviour of SOFI, as compared to other algorithms. SOFI was able to successfully identify PGs across all sets, with a large degree of agreement with other algorithms. In most cases of disagreement between algorithms, SOFI has found a higher number of symmetry elements within the specified symmetry threshold, and thus a higher order point group. In all cases where SOFI found a lower order PG than another algorithm, we have been able to retrieve the higher order PG by tuning of the symmetry thresholds parameter of SOFI.

We also present two examples of how SOFI can be utilised, other than simple identification of PGs; in the first example as a tool to generate combinations of several matrices until group completeness; and in the second example as tool to aid automatic generation of structures, and their properties (in this case a displacement vector), that transform according to the local PG symmetry about a specific atom, *i.e.* any covariant property.

One of the core ideas of SOFI is to provide a modular, and interoperable set of computational routines, which could be used for retrieving the point group symmetry properties of a structure, as standalone, or within another application. The inclusion of SOFI into the IRA library

makes it a convenient, and accessible tool for purposes related to the precise analysis of atomic structures.

SUPPLEMENTARY MATERIALS

The supplementary material contains all results of the comparison tests done in this work. The results are reported in tables and images, where the tables report the result (PG) of each algorithm included in the test for each structure, and the images serve as an overall comparison between the algorithms.

DATA AND SOURCE CODE AVAILABILITY

SOFI is released as part of the IRA library, which is under double licensing, GPL v3 and Apache v2. The source code and example programs are available at <https://github.com/mammasmias/IterativeRotationsAssignments>. Link to the online documentation is available from the main GitHub page, which includes some tutorials, and detailed descriptions

of the source code, the C-bound API, and the python interface. All data used in the comparison tests is openly available from the CCD²². All datasets and scripts used in the comparison test, and plain-text results are available from Zenodo²¹.

Appendix A: Some properties of PG symmetry matrices

The matrices θ corresponding to PG symmetry operations are orthonormal ($\theta^{-1} = \theta^T$), non-symmetric matrices with real elements, and correspond to either pure rotations (symbol C), pure reflections (symbol σ), or combinations of both (rotoreflections, symbol S).

The matrices θ_R corresponding to pure rotations (symbol C) have a positive determinant, $\det(\theta_R) = 1$, the value of trace is $Tr(\theta_R) = 1 + 2 \cos(\alpha)$, and their eigenvalues are $\lambda_1 = 1$, and $\lambda_{2,3} = \exp(\pm i\alpha)$ where α is the angle of rotation about the axis given by the eigenvector corresponding to λ_1 . A pure rotation matrix can be constructed from knowing the angle and axis of rotation, for example by the well-known Euler-Rodrigues rotation formula.

Matrices θ_F which represent pure reflection (symbol σ) are characterised by the negative determinant, $\det(\theta_F) = -1$, the value of trace $Tr(\theta_F) = 1$, and their eigenvalues are $\lambda_1 = -1$, and $\lambda_{2,3} = 1$. The normal vector of the plane of reflection is given by the eigenvector of θ_F corresponding to λ_1 . A reflection matrix can be constructed from knowing the normal vector of the plane of reflection $|x\rangle$ by $\theta_F = E - 2|x\rangle\langle x|$, where E is the identity matrix, and $|\cdot\rangle\langle\cdot|$ indicates the outer product.

Matrices θ_{RF} corresponding to rotoreflections (symbol S) are characterised by the negative determinant, $\det(\theta_{RF}) = -1$, the value of trace $Tr(\theta_{RF}) = -1 + 2 \cos(\alpha)$, and their eigenvalues are $\lambda_1 = -1$, and $\lambda_{2,3} = \exp(\pm i\alpha)$, where α is the angle of rotation about the axis given by the eigenvector of λ_1 , which is at the same time also the normal vector of the plane of reflection. Matrices corresponding to rotoreflections can be constructed from combination of pure rotation and pure reflection matrices, $\theta_{RF} = \theta_F \theta_R$, where θ_F and θ_R have the same vector as the axis of rotation, and the normal of the plane of reflection.

The angle α in radians is transformed to integers n and p , such that $\alpha/2\pi = p/n$. For instance, the rotation for 5/12th of a circle (angle 150°), would be $n = 12$ and $p = 5$.

It can be observed that the use of σ symbol for pure reflections over some axis is redundant, since an equivalent notation is a rotoreflection S with angle $\alpha = 0$. We thus label pure reflections as "S 0".

The properties listed above are synthesised in the Table II.

The slight exceptions to the above are the identity $E = \text{diag}(1,1,1)$ and the point-inversion $I = \text{diag}(-1, -1, -1)$, which have the same matrix form regardless of the orientation of the reference frame. Never-

	identity E	inversion I	rotation C	rotoreflection S
$\det(\theta)$	1	-1	1	-1
$\lambda_{1,2,3}$	1, 1, 1	-1, -1, -1	1, $\exp(\pm i\alpha)$	-1, $\exp(\pm i\alpha)$
$Tr(\theta)$	3	-3	$1 + 2 \cos(\alpha)$	$-1 + 2 \cos(\alpha)$

TABLE II. The axis of rotation (plane of reflection) is given by the eigenvector corresponding to λ_1 .

theless, the identity matrix can be seen as rotation about any axis for an angle $\alpha = 0$ (operation C 0), and the point-inversion can be seen as rotoreflection about any axis for an angle $\alpha = \pi$ (operation S 2π).

Due to the numerical procedure of matrix diagonalization, where any \pm direction is an equivalent solution for the eigenvectors (thus the axis), the relative orientation of the operation (sign of the angle α) cannot be trusted. For this reason, we follow the convention for orienting the axis such that its components are: $z > 0$, if $z = 0$ then $x > 0$, and if $x = 0$ then $y > 0$. The sign of α is then deduced with respect to this axis.

1 Algorithms and datasets used in the comparison test

All the structures, software source codes, scripts, and plain-text format of all results from the test can be downloaded from Zenodo [1].

The SOFI algorithm presented in the main article has been compared to the SYVA [2], SymMol [3], and libmsym [4] software. SYVA has been downloaded from ¹. SymMol software has been extracted from IQmol3 repository, commit 32cbf13 at ², and libmsym v0.2.3 from ³.

In order to make the tests run smoother, we had to make some small modifications to some of the source code, mostly regarding their output. The SYVA code was used completely as-is, it is limited to max 250 atoms, and we were not able to modify that limit. The SymMol code is by default limited to maximum 100 atoms, but we were able to simply modify this to our needs. Its source was also modified in one instance of integer initialisation, which was causing a crash due to segmentation fault. The output of SymMol uses the label "C3i", and "T23" for the groups "S6" and "T" respectively. The former is a possible alternative nomenclature, while we are not sure of the latter, it might simply be a typo in the code. We change all instances of these labels to "S6", and "T", after SymMol outputs them. The libmsym software has been modified as suggested in the GitHub issue #17 ⁴ to properly output the group C1, instead of an error message, when that is the case. All modifications to the source codes done for the purpose of this test are available as diff patches in the Zenodo reference [1].

The data sets containing the atomic structures used for testing the code are taken from the Cambridge Cluster Database (CCD) website [5], more specifically the sets where PG information is available. The ones used in our test are listed below, referred to by their name as it appears on the CCD website:

- Lennard-Jones clusters N=3-150 [6],
- Quantum Lennard-Jones clusters [7],
- Sutton-Chen clusters 10-8 , 9-6 , and 12-6 [8],
- Glue clusters Al, [9] , and Pb [10],
- Gupta clusters (Zn, Cd, Pb, Na) [11, 12, 13],
- Murrel-Mottram clusters (Na) [12],
- Finnis-Sinclair clusters Mo and Fe [14],
- C60 clusters [15],
- C60-Pacheco clusters [16],
- Morse clusters [17, 18, 19],

¹<https://data.mendeley.com/datasets/xd4g8hyjf2/1>

²<https://github.com/nutjunkie/IQmol3/blob/09e9f6b832e8a7cb6bde1e787a93a03993023713/src/Fortran/symmol.f90>

³<https://github.com/mcodev31/libmsym/releases/tag/v0.2.3>

⁴<https://github.com/mcodev31/libmsym/issues/17>

- Dzugutov [20], and Dzugutov-mod clusters [21],
- $(\text{NaCl})_N\text{Cl}^-$ for Coulomb/Born-Meyer and Welch potentials [22],
- binary Lennard-Jones clusters [23].

The format of the files containing atomic structures was changed into the regular xyz format, and all atomic types have been assigned to character (string) symbol values. In cases when the atomic type is not obvious (i.e. in the binary LJ, or morse dataset), H and/or He were used as surrogate symbols.

The total dataset of atomic structures thus contains 3858 structures, with number of atoms ranging from 3 to 380. The only set of structures containing more than one atomic type is the bin_LJ set, which contains two atomic types.

2 Methodology

2.1 The tolerance values

The algorithms SYVA [2], SymMol [3], and SOFI have a more or less equivalent definition of the tolerance parameter (symmetry threshold in SOFI), which is that the maximal displacement of any atom of the symmetry-transformed structure, with respect to the original structure, should be below the tolerance. Due to the equivalent definition and meaning of the tolerance value, the results of these three algorithms can be directly compared at the same value of tolerance.

We have performed the tests with the tolerance at two values, (i) with `tol=0.001`, which is the default value for the tolerance in the SYVA code, and (ii) at the value `tol=0.05`. These values were applied to the SYVA, SymMol, and SOFI algorithms. The software libmsym [4] does not have a single value for the tolerance parameter, but instead several values related to different aspects of the respective algorithm. For the present test, we took three different sets of values for the tolerance in libmsym, which are also used in the avogadro software [24], in which they are labelled as "tight" or "default", "medium", and "loose" (see link ⁵).

2.2 Reported values

For each input structure we compute the PG with a given tolerance, using each algorithm. The symbol "-" in any entry indicates a failure of the software to find any PG, where the error or failure was either reported by the code, the code has crashed with no output, or in the case of SymMol the computation has timed out.

The leading hypothesis for differences in the results of the compared algorithms is that the use of principal axes of inertia can be ambiguous when its eigenvalues are very similar. For this reason, we explicitly compute the matrix of inertia for each structure, and diagonalize it to obtain the principal axes. We then perform the scalar product between each of the principal axes of inertia, and each of the principal axes of symmetry as found by SOFI, and store the highest value of the dot product among all the possible combinations. The absolute value 1.0 of this dot product indicates that any one of the principal axes of inertia is indeed along any one of the principal axes of symmetry, while a value significantly lower than 1.0 indicates that none of the principal axes of inertia are aligned with any of the principal axes of symmetry. The value is reported in the tables under the column "dot product". For the C1 point groups, the reported value is irrelevant since the C1 group has no principal axis of symmetry.

The columns labelled N_{op} report the number of symmetry operations associated to the respective PG.

3 Results

For a more compact representation, the results are plotted in form of 2D histograms (*i.e.* Fig. S1), where each of the axes represents the result for a given atomic structure by a given algorithm, at a given tolerance value. All cases of failure are omitted from the 2D histograms. The values inside the plot are positioned such that their (x, y) position encodes the PGs resulting from each of the two algorithms, and their numerical value represents the number of input structures where such combination of PGs occurred. The values on the diagonal of the plot represent cases when the two compared algorithms returned the same result for the same structure. The off-diagonal values represent cases where the two algorithms have returned a different result.

The point groups are ordered on the axes by their order/cardinality (number of elements). All values appearing on the upper side of the diagonal indicate that the resulting PG by algorithm reported on the y -axis has a higher order than the same result with the algorithm on the x -axis, and the opposite for values below the diagonal.

⁵<https://github.com/OpenChemistry/avogadrolibs/blob/master/avogadro/qtplugins/symmetry/symmetrywidget.cpp>

In the big majority of structures, the algorithms agree among each other in the resulting PG, there are however some cases of different results. In the following sections we analyze the cases of differences, mainly from the point of view of SOFI. That is, we are not interested in analysing and resolving each particular problematic case of every algorithm, but rather only those where there is a difference with respect to SOFI. In cases where SOFI finds a lower-order PG, we find the value of tolerance needed by SOFI to obtain the same PG. In the opposite case, we do not perform any further computation. Due to this, the comparison tests performed here cannot be viewed as fair benchmarking of algorithms, but merely as a way to expose the performance of SOFI, by means of comparison to other established algorithms.

The Sections 3.1, 3.2, and 3.3 contain the comparisons to SYVA, SymMol, and libmsysm, respectively. The Section 5 lists the results of all algorithms and structures used in the test. The summary of reported failures is provided in the Tab. S8.

3.1 Comparison with SYVA

The SYVA software is by implementation limited to max 250 atoms, we thus ignore all structures with more than 250 atoms, they are not included in the following analysis.

Figure S1: Comparison of SYVA and SOFI at (left) $tol = 0.001$, and (right) $tol = 0.05$.

3.1.1 Value $tol = 0.001$

The case with $tol = 0.001$ is shown on Fig. S1(left). All the resulting PGs agree with the result of SYVA($tol = 0.001$), except the five cases listed in Tab. S1, which we analyzed further:

set	struc name	SYVA	N_{op}	SOFI	N_{op}	dot product	needed tol
glue_Pb	54	–	0	S10	10	1.00000	
gupta/Co	174	Cs	2	C1	1	1.00000	0.00131
gupta/Co	183	–	0	C2	2	1.00000	
gupta/Co	190	D5	10	D5h	20	1.00000	
QLJ	75A	Cs	2	C1	1	0.96203	0.0014

Table S1: Cases of different results between SYVA and SOFI at $tol = 0.001$. There are two cases of failure by SYVA. In cases where SYVA has found a PG with a higher order, the column labelled "needed tol" indicates the value of tol such that SOFI(tol) retrieves the same PG as SYVA.

- structure glue_Pb:54, SYVA reports "unable to determine PG", however the symmetry operations that it reports correspond to point group S10. SOFI reports group S10.

- structure Gupta/Co:174, SYVA reports group Cs, while SOFI reports group C1. The S0 symmetry operation that is missed by SOFI($tol = 0.001$) is found with SOFI($tol = 0.00131$).
- structure Gupta/Co:183, SYVA reports 3 symmetry operations, but reports a failure to find PG. SOFI($tol = 0.001$) reports 2 symmetry operations and the group C2. The extra symmetry operation found by SYVA($tol = 0.001$) is found by SOFI($tol = 0.0012$), which finds an additional symmetry for the group C2v.
- structure Gupta/Co:190, SYVA find D5, SOFI finds D5d-, and D5h after combinations, with maximal distortion value 0.0012.
- structure QLJ:71A, SYVA finds Cs, SOFI finds C1. The S0 symmetry missed by SOFI($tol = 0.001$) is retrieved with SOFI($tol = 0.0014$).

Upon some analysis of the SYVA source code, we find a table of hard-coded point groups, and the group S10 is not among them (see file `blockdata.f` in SYVA source). It also seems like SYVA does not attempt to deal with slightly broken symmetries (as in structure Gupta/Co:183), but instead directly reports a failure.

Henceforth we skip listing and analysing any of the reported failures.

3.1.2 Value $tol = 0.05$

set	struc name	SYVA	N_{op}	SOFI	N_{op}	dot product	needed tol
glue_Al	134	C2v	4	C2	2	1.00000	0.059
glue_Al	181	C2v	4	Cs	2	1.00000	0.062
glue_Al	183	Cs	2	C1	1	1.00000	0.061
gupta/Co	37	C2	2	C1	1	0.99998	0.051
gupta/Na	246	D5	10	C5	5	1.00000	0.051
murrel-mottram/Na	109	Cs	2	C1	1		
murrel-mottram/Na	112	Cs	2	C1	1		
murrel-mottram/Na	113	Cs	2	C1	1		
murrel-mottram/Na	120	C2v	4	C2	2	1.00000	
NaCl_N/CBM	15	Cs	2	C1	1		

Table S2: Cases of different results between SYVA and SOFI at $tol = 0.05$. There are 290 cases of failure by SYVA. In cases where SYVA has found a PG with a higher order, the column labelled "needed tol" indicates the value of tol such that SOFI(tol) retrieves the same PG as SYVA.

In the case of $tol = 0.05$, the number of differences between SYVA and SOFI is 10. The number of failures reported by SYVA($tol = 0.05$) is 290, without counting the structures with more than 250 atoms. The cases of different results are given in the Tab. S2.

In the last 5 cases of the Tab. S2 (the murrel-mottram and NaCl_N cases), SYVA has returned a PG of higher order than SOFI, and we were not able to determine the value of tol for which SOFI(tol) would retrieve the same groups. Upon further inspection into these cases, the symmetry operations in the SYVA output seem unconventional, for example the reported axes of symmetry are far from normalized (normally the axes output by SYVA are normalized), the angles of rotation have peculiar values such as 179.95 degrees (which we have not observed in other SYVA outputs). These observations make us suspect a possible (unknown) software bug in SYVA, which might be further supported by the fact that none of the included software reports the groups found by SYVA for these structures, at any tolerance value (see the complete results in Sec. 5, namely the corresponding entries in Tables S45, S46, and S50). In fact, all other software agree in the resulting PG.

3.2 Comparison with SymMol

In some cases, the SymMol software seems to get trapped in what appears to be an infinite loop (a process that never terminates). To mitigate this, we constrain every call to SymMol with a timeout value of 10 seconds. If a computation takes more than 10 seconds, the call is terminated and result recorded as failure.

SymMol software labels the S6 group as C3i. We have changed all occurrences of C3i in the results into S6, a-posteriori.

3.2.1 Value $tol = 0.001$

The number of different results between SymMol($tol = 0.001$) and SOFI($tol = 0.001$) is 225, where in all cases SOFI has found a higher order PG than SymMol. On top of that, the number of cases where SymMol fails due to the timeout constraint is 112. We skip listing all these cases here, but they could easily be filtered from all the results.

Figure S2: Comparison of SymMol and SOFI at (left) $tol = 0.001$, and (right) $tol = 0.05$.

3.2.2 value $tol = 0.05$

set	struc name	SymMol	N_{op}	SOFI	N_{op}	dot product	needed tol
glue_Al	134	C2v	4	C2	2	1.00000	0.059

Table S3: Case of higher-order symmetry obtained by SymMol than SOFI at $tol = 0.05$. The column labelled "needed tol" indicates the value of tol such that $SOFI(tol)$ retrieves the same PG as SymMol.

The number of different results between $SymMol(tol = 0.05)$ and $SOFI(tol = 0.05)$ is 221, where in all cases except for one, SOFI has found a higher order PG than SymMol. The single case where $SymMol(tol = 0.05)$ found a higher order symmetry is reported in Tab. S3. With the modified tolerance, $SOFI(tol = 0.059)$ retrieves the C2v group reported by $SymMol(tol = 0.05)$. On top of that, the number of cases where SymMol fails due to the timeout constraint is 112.

3.2.3 General observations

set	name	SYVA		SymMol		libmsym			SOFI		dot product

sutton_12_6	55	Ih	Ih	Ci	Ci	Ih	Ih	Ih	Ih	Ih	0.97111

Table S4: Cases where SymMol fails to recognize the Ih point group.

It is worth noting that the SymMol algorithm seems to have some trouble in recognising the Ih group. Out of 53 structures in the dataset where Ih group appears, SymMol only recognizes 27 of them correctly, even when all other algorithms seem to agree on the Ih group. Moreover, SymMol systematically labels these as the Ci group. All such

cases are noted in the Tab. S4. It is also worth noting that in many of these cases, the value of "dot product", which is the maximal scalar product between the symmetry axes and the principal axes of inertia, is below 1.0. This is significant since there are 6 principal axes of symmetry in the Ih group, and none of them seem to perfectly align with any of the principal axes of inertia. Based on this data, one could make a statement about the idea of basing the identification of symmetry axes solely on the inertial axes, or more precisely a statement about the ambiguity of such procedure.

3.3 Comparison with libmsym

Since the libmsym software has a completely different definition of tolerance, we cannot directly compare the obtained value. We thus compare each of the three sets of tolerance values used in libmsym, with each of the two tolerance values used in SOFI.

3.3.1 libmsym(*tol* = "default")

Figure S3: Comparison of libmsym(*tol* = "default") with (left) SOFI(*tol* = 0.001), and (right) SOFI(*tol* = 0.05).

There are 20 cases of failure of libmsym(*tol* = "default"), the number of cases where SOFI(*tol* = 0.001) found a higher-order PG than libmsym(*tol* = "default") is 18, while in 23 cases libmsym(*tol* = "default") found a higher-order PG. The latter 23 cases are listed in Tab. S5. We can observe that SOFI can retrieve the PG found by libmsym in all the cases, by setting a slightly higher tolerance value.

In case of SOFI(*tol* = 0.05), there are 57 differences with respect to libmsym(*tol* = "default"), in all of which SOFI has found a higher-order PG than libmsym.

3.3.2 libmsym(*tol* = "medium")

At the "medium" tolerance level, libmsym reports a failure for 227 cases. The number of cases where SOFI(*tol* = 0.001) produces a higher-order PG than libmsym(*tol* = "medium") is 33, while vice-versa the number of cases is 28. The latter 28 cases are reported in Tab. S6.

With SOFI(*tol* = 0.05) there are 58 cases where SOFI finds a higher-order PG, and 3 cases where libmsym(*tol* = "medium") finds a higher-order PG. These 3 cases can be inferred from Tab. S6, as the cases where "needed *tol*" is beyond 0.05, namely structures in the glue_Al set, 79, 134, and 183. It can be observed that all of those can be retrieved in SOFI by raising the tolerance.

3.3.3 libmsym(*tol* = "loose")

With the libmsym(*tol* = "loose"), there are 782 failures reported by libmsym. In 82 cases SOFI(*tol* = 0.001) has found higher-order PG, while in 37 cases libmsym(*tol* = "loose") found a high-order PG.

set	struc name	libmsym	N_{op}	SOFI	N_{op}	dot product	needed tol
gupta/Co	174	Cs	2	C1	1	1.00000	0.0014

murrel-mottram/Na	222	C3	3	C1	1	1.00000	0.0024
murrel-mottram/Na	232	D3	6	C1	1	1.00000	0.0014
murrel-mottram/Na	242	C2	2	C1	1	1.00000	0.0029
murrel-mottram/Na	321	Cs	2	C1	1	1.00000	0.0017
murrel-mottram/Na	327	C2v	4	Cs	2	1.00000	0.002
QLJ	75A	C5v	10	C1	1	1.00000	0.0053

Table S5: Cases of higher-order symmetry obtained by libmsym($tol = "default"$) than SOFI($tol = 0.001$). The column labelled "needed tol" indicates the value of tol such that SOFI(tol) retrieves the same PG as libmsym.

Figure S4: Comparison of libmsym($tol = "medium"$) with (left) SOFI($tol = 0.001$), and (right) SOFI($tol = 0.05$).

When using SOFI($tol = 0.05$), there are 93 cases where SOFI finds a higher-order PG, and 13 cases where libmsym($tol = "loose"$) finds a higher-order PG. All these 13 cases can be inferred from Tab. S7, as cases where the "needed tol" exceeds 0.05. It can also be observed that for all these cases, SOFI can retrieve the higher-order PG with an appropriate value of tol .

Table S6: Cases of higher-order PG obtained by `libsym(tol = "medium")` than `SOFI(tol = 0.001)`. The column labelled "needed tol" indicates the value of `tol` such that `SOFI(tol)` retrieves the same PG as `libsym`.

Figure S5: Comparison of `libsym(tol = "loose")` with (left) `SOFI(tol = 0.001)`, and (right) `SOFI(tol = 0.05)`.

4 Discussion

The tolerance value as defined and used by SYVA, SymMol, and SOFI is based on real distances between the atoms. Thus, such value can scale with the scale of the structure (interatomic distances). As noted in the main article of SOFI, as a rule of thumb, the tolerance value can be chosen as up to about half the nearest neighbor distance. In all the structures included in the present comparison test, the nearest neighbor distance is well beyond the used tolerance values $tol = 0.001$ and $tol = 0.05$. This comparison test does not go deeper into investigation of the tolerance value, or its relationship to the nearest neighbor distance. A preprocessing procedure to determine the largest sensible tolerance value could potentially be very useful for these algorithms, since it could be used to determine the highest-order PG of a structure, from which the subgroups with a more stringent tolerance could easily be extracted by a postprocessing.

Throughout the test, we observe minor differences in the values of distortion (i.e. score, or distance), in terms of the distance value, for the symmetry operations reported by different algorithms (where the data is available). These could be explained by the different ways algorithms find and set the axes of each symmetry operation, which could result in minor differences in the actual matrix representation of the operation, which in turn leads to small differences in the symmetry-transformed structures, and thus slightly different values of the distance computed between the original, and the symmetry-transformed structure.

It appears that SYVA and `libsym` algorithms do not attempt to deal with incomplete groups (in the sense

Table S8: The count of failures of each algorithm and tolerance value used. Failures are counted only for cases when the output of an algorithm actually reports a failure, or the program crashes. For SYVA, the count does not include structures with more than 250 atoms. For SymMol the count includes cases of timed-out computations.

of group completeness), but rather just report a failure. On the other hand, it is possible that SymMol performs combinations of elements with the goal of group completeness. We have not found a routine explicitly dedicated to that in SymMol, but we also did not spend much time investigating the source code. In SOFI, the incomplete groups are explicitly labelled with + or - signs, which are related to the number of actual elements, and the expected number of elements for a PG identified via flowchart. These cases can optionally be explicitly made into complete groups, via combinations of the symmetry elements.

The comparison tests performed in this paper show that the developed SOFI algorithm is capable of identifying the PG symmetry in atomic structures. Among all the structures and tolerance values included in the test, there is no case of failure of SOFI, contrary to other algorithms (See Tab. S8). In all cases of disagreement between algorithms, SOFI is capable to find a PG of the same order, or higher, when computed with an appropriate tolerance value.

5 All results

The following Tables contain the results by each algorithm used, at each tolerance value, for each structure in the dataset. The first column reports the exact name of the structure as it appears in the dataset, the column marked "diff" contains an exclamation mark (!) if there is a disagreement between the algorithms, and the letter "M" if the PG assignment changes with raising the threshold value.

They are separated by dataset, as follows. Bin LJ results in Tab. [S9](#), [S10](#), [S11](#), [S12](#), [S13](#), and [S14](#). C60 and C60-Pacheco results in Tab [S15](#), and [S16](#). Dzugutov and Dzugutov_mod results in Tab. [S17](#), [S18](#), [S19](#), and [S20](#). Finnis-Sinclair results in Tab [S21](#) and [S22](#). Glue results in Tab [S23](#), and [S25](#). Gupta results in Tab [S27](#), [S28](#), [S29](#), [S30](#), [S31](#), [S32](#), [S33](#), [S34](#), [S35](#), [S36](#), [S37](#), and [S38](#). LJ results in Tab. [S39](#), and [S40](#). Morse results in Tab [S41](#), [S42](#), [S43](#), and [S44](#). Murrel-Mottram in Tab [S45](#), [S46](#), [S47](#), [S48](#). NaClN results in Tab. [S49](#), and [S50](#). Quantum LJ results in Tab. [S51](#). Sutton results in Tab [S52](#), [S53](#), and [S54](#).
